Dr. Collings, it is true, mentions that "Many practitioners now regard the promise of health centres as a political trick, designed to gain their support at the time of the negotiations, or at least as an unfulfilled promise whose fulfilment is now unlikely." He does not, I think, realise how great was the disillusionment and resentment felt especially by the young doctors who had been promised, in section 21, lavish equipment and specially designed premises, and, counting upon this promise, ceased to trouble themselves about these two items.

The manner in which the Minister broke the promises contained in section 21 of the Act aggravated the anger of the profession. The undertaking was broken by the unobtrusive method of a circular (no. 3, Jan. 14, 1948)—and it is to be noted that circulars do not require, as do regulations, to be laid before Parliament. The Minister secured the virtual repeal of section 21, and this exercise of dictatorial power constitutes a new advance on the road to totalitarianism. I believe it to be without precedent that it should be within the power of a Minister, without reference to Parliament, and with no authority other than his own fiat, to annul a section of an Act of Parliament already on the statute-book, described by the Minister himself as "a key feature in the reconstruction of the country's health services."

The non-provision of the promised health centres has roused strong protests from every part of the House, and it is significant that the trade unions, through the T.U.C., are now demanding the immediate provision of 100 health centres. A recent Parliamentary answer (*Hansard*, March 23, 1950) revealed that since the passage of the Act in 1946, as regards health centres, "one new building is under construction; one other new building and one adaptation have been approved." The provision of health centres is obviously relegated to the Greek calends.

The Athenæum, London, S.W.1. E. GRAHAM-LITTLE.

SIR,—Whatever its merits as a quantitative survey, as a qualitative survey, the Collings report has not so far been effectively challenged. This being so, it deserves very serious discussion among medical students, many of whom will be influenced by its conclusion.

[illegible] the experience of most of us that though [illegible] the formative period in a warm and [illegible] the humane and most satisfying calling [illegible] of every man built by the [illegible] of those of us who come from medical [illegible] the view of general practice which is [illegible] by the teaching hospitals, where the [illegible] practice is concerned. On the contrary, [illegible] formerly the least satisfying and the [illegible] field of medicine. The only justifica-[illegible] of general practice is that there [illegible] with enormous difficulties, which it [illegible] become more impossible to deal with by [illegible] of the highest integrity; and it is [illegible] for any man in his right mind to meddle [illegible] if he is not compelled by circumstances.

[illegible]-minded students are to be turned to this [illegible] it is no use to conceal the real situation [illegible]. Unfortunately, during their formative period, [illegible] they are still able to think of changing the conditions and limitations of general practice, they are [illegible] isolated from this aspect of medicine, and in [illegible] cases their own previous background gives them [illegible] personal experience, as a patient, of the typical [illegible]-class practice.

If there is to be a decisive turn to coöperative forms of practice, as Dr. Collings suggests, it is essential that the medical curricula provide means by which students can appreciate the limitations and possibilities of general practice, at a time when it would be impossible for them to reconcile themselves to the dual standards applied in the average industrial practice on the one hand, and the teaching hospital on the other. At the same time they would more readily appreciate that the practice of medicine is conditioned as much by housing, wages, old-age pensions, and the like, as by the latest advances in hospital treatment.

Medical School, St. George's Hospital. J. TUDOR HART.

SIR,—The main value of the Collings report is that it will enable the general public to have a better idea of the poor return obtained for the heavy expenditure on medical services. The poor return is not confined to the general-practitioner service, and a report on part-time consultants will reveal similar widespread low standards of practice—standards which will continue as long as the majority of doctors regard their patients as mere capitation fees or as providers of "sessions."

The common attitude to patients is colourfully put by Dr. French (April 8) whose "nauseating" surgeries were full of "depressing faces with their owners sitting on hyperkeratinised bottoms." It is amazing that a doctor should rush into print to express such an attitude, for he thereby shows that he has completely failed in his responsibilities to his patients. That surgeries are overcrowded is almost entirely the fault of general practitioners themselves, who, for fear of the loss of a capitation fee, will forgo an honest approach to patients' problems and fob them off with a tonic or placebo. The patient, with continued frustration and anxiety, returns in another vain seeking for help; but the practitioner, encouraged by such writings as those of Dr. Gooddy (Feb. 11), regards this as confirming his belief that the patient is only trying to get "something for nothing."

The recent B.M.A. booklet on Ethics states that "the [illegible] position of privilege in [illegible]nding that a doctor's [illegible]cause in the past the [illegible] of placing the needs [illegible] the basis on which [illegible] *disappeared*, the [illegible]d and the only [illegible]re is a full-time salaried service with an inspectorate to ensure that the doctor effectively carries out the duties for which the people of this country pay him such enormous sums of money.

Shenley. E. TRUMAN.

SIR,—No informed and unbiased practitioner is able to deny Dr. Collings's statement that "the conditions and standard of general practice in industrial areas make a mockery of our modern medical education and the disciplines and practices taught in our great hospitals." In seeking a remedy, two premises must, in my view, be accepted. The first is that it is difficult to influence the standard of general practice adequately from within; and the second, that our medical schools have yet to recognise that the problems and standards of general practice cannot be outside their responsibility.

As one who has been in general practice for a number of years, I am convinced that no general practitioner will admit that any other is better than he, whatever his colleague's degrees, experience, or standard of work. Practitioners are individualists, usually isolated from any work but their own. Unaided, no general-practitioner organisation can hope to redeem the position. Few of their members who have been in practice for over seven years can hope to regain teaching-hospital standards of case-taking, treatment, and knowledge of recent work. Moreover any body of practitioners would be distressed if they had to recommend standards unattainable by the majority of their members under existing conditions.

Improvement will come rather through: (1) a better-informed public, demanding higher standards; and (2) the coöperation of the medical schools, which all practitioners hold in high regard. To my mind the essential remedy is not material—in the form of health centres, equipment, and so on—but vocational. General practice requires a "spill-over" of the high scientific ideals and the [illegible] drive and sense of vocation that permeates our medical schools—a spirit that would be fostered by the experience gained by the consultants as a result of the intimate personal relationships and the vocational service possible under the hard disciplines of general practice. The medical schools can take two practical steps, neither of which would involve large cost or long delay. First, the future teachers of medicine could be encouraged to spend a period in general practice; for future practitioners ought to be taught as students by men and women who have had some experience in this field. Some of the general-practitioner trainee grants could well be diverted to this end. At the moment the money devoted to these grants is lavish: if half the amount were offered, principals would still be eager to get trainee assistants. Assured that the time spent "in the field" would not count against their academic advancement (as it may at present), registrars might be glad to spend 6–12 months in practice before taking a senior appointment. One effect would be the gradual elimination of the unsympathetic attitude to general practice which is found in all medical schools, and which accounts for young doctors turning reluctantly to this work only when they see that other roads are barred to them.

Secondly, medical schools can coöperate on a small scale with general practitioners. Junior clinical staff—e.g., surgical and medical registrars—could work for a short time each week in a general practice which applied for this help. During the period of this coöperation, the general practitioner should be given the privilege of direct access to the special departments of the hospital for those of his patients who require investigation. Both sides would gain: the hospital staff, because the clinical material and problems are different outside hospital; and the practitioner, because he could discuss with a member of the hospital staff cases at the start [illegible]d of investigation.

This was the first vitamin ever to
Haworth gave it its name of "ascorbic
In collaboration with his colleague,

13. Weingarten, R. J. *Lancet*, 1943, i, 103; *Ind.* 369.
14. Loeffler, W. *Beitr. Klin. Tuberk.* 1932, 79, 338; *Med. Kinderheilk.* 1943, 63, 195.

I believe that practitioners as a whole would soon wish to take advantage of this system, once instituted; for they cannot fail to respond when a nearby practice is offering a better service. After a certain length of time the activities of the hospital could be directed to another practice.

Who, it may be asked, is to guide and coördinate such a plan for practitioners and the medical schools? One's mind turns to the Central Health Services Council, even though there has been little hint that this body is alive to the problems of general practice. The status of general practice is the most important problem of modern medicine. Too long general medical practice and our medical schools have been separated by a gulf, which now grows wider. To close this gulf is the only remedy for preser [illegible] ards. This requires a spirit of [illegible] and of vocation and initiative—not the dry bones of organisation and high finance. My claim is that the suggestions I have put forward are practicable, that they can be started in a small way by personal arrangement, and that it is only along such lines that general practice will fulfil its high purpose.

Parliament

N.H.S. Superannuation Regulations

IN the House of Commons on March 30 Mr. ARTHUR BLENKINSOP, parliamentary secretary to the Ministry of Health, moved that the Draft National Health Service (Superannuation) Regulations 1950 be approved. He said that though these regulations in the main simply [illegible] ast had been dealt with through [illegible], they did make certain changes. The most important change was that covered by regulations 28 and 30 which proposed to give a further option to join the State scheme to those who, when it was originally introduced, decided to remain outside. The new regulation 28 and regulation 47 also made for greater freedom of movement between the central and local health services. Regulation 46 had also been amended to exempt the general practitioner who employed an assistant from liability for the employer's contribution for the assistant. This would throw some extra charge on the Exchequer, but the Government felt that it was a reasonable adjustment in the arrangements between the Exchequer and the general practitioners.

Lieut.-Colonel WALTER ELLIOT hoped that the Minister would consider whether some temporary reopening of the books could not take place for the outward movements in the same way as he was allowing it for the inward movements. He was sure that Mr. Bevan did not wish to collect people into the National Health scheme who would be happier under the Federated scheme.

Dr. CHARLES HILL welcomed the regulations. Any practitioner now contemplating holy matrimony, he said, would no longer have to engage in complicated mathematics to see what effect the margin of age between the practitioner and his bride would have on the widow's pension in certain circumstances. Further, the Minister had removed an anomaly under which the widow who was herself a practitioner was no longer prevented from enjoying the widow's pension as well as such pension as she had herself earned. He also supported the pleas for further consideration of the two-way option. The choice before the House that night was to affirm or not to affirm the whole of these regulations embodying the consolidation and change of some 28 regulations. He suggested that in future, now that the fluid stage was over, superannuation should be dealt with by dissecting out the principles from the details and embodying the principles in a Bill which could be discussed in detail by the House.

Mr. BLENKINSOP, replying to the debate, said that the one-way option would apply to 46,000 people. Were they to make it a two-way option they would have to revive an option for some 140,000 which he suggested would be administratively impracticable. He appreciated that there must be some cases of hardship, and the Minister had already found ways of dealing with certain individual cases brought to his notice. He would be very willing to adopt a similar attitude to any other such cases. The motion to approve the regulations was agreed to.

In moving the regulations for Scotland Miss MARGARET HERBISON, joint under-secretary of State for Scotland, said that they included one addition to the English regulations. This allowed the Secretary of State to make supplementary payments to certain doctors in the Highlands and Islands Medical Service scheme who decided to leave a practice in the Highlands and Islands, so long as they continued to serve under the National Health scheme. The Highland practices often covered large territories, where a doctor had to travel not only by car but by boat. It was very possible that as a doctor became older his work got beyond his physical capacity. It was not desirable that a doctor should remain in practice because of the fear that he would lose his supplementary payment. There were only about 50 of these doctors who could benefit from this further provision.

National Assistance Rates

DR. EDITH SUMMERSKILL, Minister of National Insurance, made the following statement in the House of Commons on April 4: I am informed by the National Assistance Board that they will be sending me next week draft regulations proposing increases in their current rates. I hope to be able to submit the necessary regulations for the approval of the House shortly after the recess. I understand that under these proposals the weekly rate for single householders will be increased from 24*s.* to 26*s.* and that for a married couple from 40*s.* to 43*s.* 6*d.*, in both cases exclusive of rent, with corresponding increases in other rates. The additional cost of the proposals, allowing for attraction of new cases over a period, may be expected to approach £10 millions in a full year.

The Old Folk at Home

In the House of Lords on April 5 Lord SALTOUN suggested that the measures for coping with the necessities of solitude and old age taken under the recent Acts and the reorganisation of the social services were either defective or ineffective. It was not a question of wealth or poverty. In fact the people who were in receipt of public assistance were probably better off in many respects than the well-to-do. He proposed that local authorities should be empowered to pay 2 or 3 guineas a week to relatives who had an old person living with them, for these relatives had no longer any duty in law to maintain their old people. As it cost at least 7 guineas a week to keep an old person in hospital, it would be cheaper for the public and better for the old people if they could be kept with their relatives. Lord Saltoun was especially concerned for old people living alone. Though the local authority now had power to remove these old people to homes when necessary, there seemed to him to be no organisation for what was really more important—to obtain early information of cases likely to give trouble and to arrange for regular visits to them. It was mainly a problem of the towns and he thought there should be welfare officers with small districts who would be responsible, as was the old relieving officer, for ferreting out these cases. Visiting he believed might usefully and suitably be undertaken by voluntary associations.

Lord AMULREE agreed that there was often difficulty in getting old people into hospital for they tended to occupy a bed for a long time and some authorities preferred to take in more people rather than admit those who were going to remain for a long time. But there was a change of mind coming, certainly in the medical profession, because it had been found possible to rehabilitate many of these old people so that they might at least be discharged from hospital, but the improvement in their treatment made it essential that there should be homes to which they could be sent on their discharge. He believed that Rochdale had already established a large number of homes of this kind.

It must be the experience of most of us that though we often hear general practice praised in a vague and general way as the highest and most satisfying calling in medicine, this is contradicted at every turn both by the home experience of those of us who come from medical families, and by the view of general practice which is in fact adopted by the teaching hospitals, where the working-class practice is concerned. On the contrary, general practice is obviously the least satisfying and the most frustrating field of medicine. The only justification for this mythology of general practice is that there one is indeed faced with enormous difficulties, which all the time become more impossible to deal with by individuals even of the highest integrity; and it is accounted a virtue for any man in his right mind to tackle such a problem, if he is not compelled by circumstances to do so.

If serious-minded students are to be turned to this field of work, it is no use to conceal the real situation from them. Unfortunately, during their formative period, while they are still able to think of changing the conditions and limitations of general practice, they are completely isolated from this aspect of medicine, and in most cases their own previous background gives them no personal experience (as a patient) of the typical working-class practice.

If there is to be a decisive turn to coöperative forms of practice, as Dr. Collings suggests, it is essential that the medical curricula provide means by which students can appreciate the limitations and possibilities of general ractice, at a time when it would be impossible for them o reconcile themselves to the dual standards applied n the large industrial practice on the one hand, and the teaching hospital on the other. At the same time they would more readily appreciate that the practice of medicine is conditioned as much by housing, wages, old-age pensions, and the like, as by the latest advances in hospital treatment.

Parliament

N.H.S. Superannuation Regulations

IN the House of Commons on March 30 Mr. ARTHUR BLENKINSOP, parliamentary secretary to the Ministry of Health, moved that the Draft National Health Service (Superannuation) Regulations 1950 be approved. He said that though these regulations in the main simply consolidated what in the past had been dealt with through three separate documents, they did make certain changes. The most important change was that covered by regulations 28 and 30 which proposed to give a further option to join the State scheme to those who, when it was originally introduced, decided to remain outside. The new regulation 28 and regulation 47 also made for greater freedom of movement between the central and local health services. Regulation 46 had also been amended to exempt the general practitioner who employed an assistant from liability for the employer's contribution for the assistant. This would throw some extra charge on the Exchequer, but the Government felt that it was a reasonable adjustment in the arrangements between the Exchequer and the general practitioners.

Lieut.-Colonel WALTER ELLIOT hoped that the Minister would consider whether some temporary reopening of the books could not take place for the outward movements in the same way as he was allowing it for the inward movements. He was sure that Mr. Bevan did not wish to collect people into the National Health scheme who would be happier under the Federated scheme.

Dr. CHARLES HILL welcomed the regulations. Any practitioner now contemplating holy matrimony, he said, would no longer have to engage in complicated mathematics to see what effect the margin of age between the practitioner and his bride would have on the widow's pension in certain circumstances. Further, the Minister had removed an anomaly under which the widow who was herself a practitioner was no longer prevented from enjoying the widow's pension as well as such pension as she had herself earned. He also supported the pleas for further consideration of the two-way option. The choice before the House that night was to affirm or not to affirm the whole of these regulations embodying the consolidation and change of some 28 regulations. He suggested that in future, now that the fluid stage was over, superannuation should be dealt with by dissecting out the principles from the details and embodying the principles in a Bill which could be discussed in detail by the House.

Mr. BLENKINSOP, replying to the debate, said that the one-way option would apply to 46,000 people. Were they to make it a two-way option they would have to revive an option for some 140,000 which he suggested would be administratively impracticable. He appreciated that there must be some cases of hardship, and the Minister had already found ways of dealing with certain individual cases brought to his notice. He would be very willing to adopt a similar attitude to any other such cases. The motion to approve the regulations was agreed to.

In moving the regulations for Scotland Miss MARGARET HERBISON, joint under-secretary of State for Scotland, said that they included one addition to the English regulations. This allowed the Secretary of State to make supplementary payments to certain doctors in the Highlands and Islands Medical Service scheme who decided to leave a practice in the Highlands and Islands, so long as they continued to serve under the National Health scheme. The Highland practices often covered large territories, where a doctor had to travel not only by car but by boat. It was very possible that as a doctor became older his work got beyond his physical capacity. It was not desirable that a doctor should remain in practice because of the fear that he would lose his supplementary payment. There were only about 50 of these doctors who could benefit from this further provision.

National Assistance Rates

DR. EDITH SUMMERSKILL, Minister of National Insurance, made the following statement in the House of Commons on April 4: I am informed by the National Assistance Board that they will be sending me next week draft regulations proposing increases in their current rates. I hope to be able to submit the necessary regulations for the approval of the House shortly after the recess. I understand that under these proposals the weekly rate for single householders will be increased from 24s. to 26s. and that for a married couple from 40s. to 43s. 6d., in both cases exclusive of rent, with corresponding increases in other rates. The additional cost of the proposals, allowing for attraction of new cases over a period, may be expected to approach £10 millions in a full year.

The Old Folk at Home

IN the House of Lords on April 5 Lord SALTOUN suggested that the measures for coping with the necessities of solitude and old age taken under the recent Acts and the reorganisation of the social services were either defective or ineffective. It was not a question of wealth or poverty. In fact the people who were in receipt of public assistance were probably better off in many respects than the well-to-do. He proposed that local authorities should be empowered to pay 2 or 3 guineas a week to relatives who had an old person living with them, for these relatives had no longer any duty in law to maintain their old people. As it cost at least 7 guineas a week to keep an old person in hospital, it would be cheaper for the public and better for the old people if they could be kept with their relatives. Lord Saltoun was especially concerned for old people living alone. Though the local authority now had power to remove these old people to homes when necessary, there seemed to him to be no organisation for what was really more important—to obtain early information of cases likely to give trouble and to arrange for regular visits to them. It was mainly a problem of the towns and he thought there should be welfare officers with small districts who would be responsible, as was the old relieving officer, for ferreting out these cases. Visiting he believed might usefully and suitably be undertaken by voluntary associations.

Lord AMULREE agreed that there was often difficulty in getting old people into hospital for they tended to occupy a bed for a long time and some authorities preferred to take in more people rather than admit those who were going to remain for a long time. But there was a change of mind coming, certainly in the medical profession, because it had been found possible to rehabilitate many of these old people so that they might at least be discharged from hospital, but the improvement in their treatment made it essential that there should be homes to which they could be sent on their discharge. He believed that Rochdale had already established a large number of homes of this kind.

Lord WEBB-JOHNSON pointed out that the difficulty of finding a hospital-bed for an old person was not a new one—it had been a problem to his own knowledge for the last half century. He agreed that the right solution was wherever possible to help the younger generation to keep their old folk in their own homes.

Lord KERSHAW claimed that the introduction of the National Health Service and the new National Assistance scheme had greatly improved the care of old people; but he agreed that in the evolution of a new scheme defects might well appear. It was often suggested, for instance, that the new Acts had created a division of responsibility. But he believed the National Assistance Board through their officers were in sufficient touch with the old people whom they were helping, while the fact that everyone was now entitled to free medical service made it less likely that anyone could suffer in silence or alone. He admitted that there were many old people who should be in an institution. But 5000–6000 beds of the 57,000 available for the chronic sick were unoccupied because of lack of nurses. That was roughly the number of elderly people who would be the better for hospital treatment. Without claiming that it was perfect, he did feel that the present system had diminished the possibility of old people suffering in loneliness.

QUESTION TIME

Purchase-tax on Hospital Equipment

Mr. ANTHONY GREENWOOD asked the Minister of Health what was the amount spent on surgical and medical requirements by regional hospital boards and teaching hospitals in England and Wales during the last convenient period of 12 months; and what proportion of that expenditure was attributable to purchase-tax.—Mr. ANEURIN BEVAN replied: The revised estimates of regional hospital boards and teaching hospitals in England and Wales show that for the year ending March 31, 1950, the amount spent on medical and surgical requirements will be about £13,280,000. The proportion of this expenditure attributable to purchase-tax is not known but is thought to be quite small.

Replying to Sir IAN FRASER, Mr. BEVAN said he did not intend to publish accounts of individual hospitals, or of hospital groups, but as required by section 55 (4) of the National Health Service Act summarised accounts of the hospital service would be presented to Parliament annually.

Cost of Drugs and Medicines

Mr. R. S. RUSSELL asked the Minister the total cost of drugs and medicines supplied under the National Health Service up to the most recent convenient date; what proportion of this total cost was in respect of proprietary medicines; and how much of the cost was due to purchase-tax. —Mr. BEVAN replied: The total amount paid to chemists and doctors up to Feb. 28, 1950, for supplying drugs under the general medical and pharmaceutical services was about £43¹/₄ million. It is estimated that at the rate at which proprietary medicines are now being prescribed they account for rather more than 30% of the current cost. It is estimated that purchase-tax accounts for about 1% of the total cost.

Replying to Mr. EMRYS HUGHES, who asked what new proposals he had to prevent the exploitation of the public by vendors of patent medicines, Mr. BEVAN said that the general question of prescribing proprietary preparations was under consideration by a special subcommittee of the Central and Scottish Health Services Councils.

Purchase-tax on Proprietary Medicines

Mr. A. C. BOSSOM asked the Chancellor of the Exchequer what proportion of the retail price of the majority of proprietary medicines was taken by his Department in purchase-tax, tax from the manufacturer, wholesaler, and retailer. —Mr. DOUGLAS JAY replied: The average incidence of purchase-tax on chargeable proprietary medicines is approximately 20% of the retail selling price.

Diabetic Patients and Sugar Tests

Mr. WILLIAM TEELING asked the Minister of Health whether he was aware that some diabetic patients were unable, by reason of physical infirmity, to make use of sugar tests by means of Benedict solution; and whether, for that reason, he would ensure that 'Clinitest' sets and tablets are equally made easily available under the National Health scheme. —Mr. BEVAN replied: Yes Sir, and I intend to do this.

Dangers of New Insecticides

Mr. E. G. GOOCH asked the Home Secretary if he was aware of the dangers to agricultural workers involved in the use of some of the new insecticides, particularly D.N.O.C., dinitro-orthocresol, and 'Parathion,' diethyl-*para*-nitrophenylthiophosphate, both used as sprays for crop protection and deadly in their effect upon man; and if he would ban their use.—Mr. CHUTER EDE replied: The Poisons Rules, which control the sale of these valuable insecticides provide for a warning notice on the containers in which they are sold, and I am advised that if reasonable care is taken there is little or no risk in their use.

Silicosis in South Wales

Mr. DAVID WILLIAMS asked the Minister of National Insurance how many miners in South Wales applied for disablement certificates to the Silicosis Board in 1949; how many were certified; and what were the corresponding figures for 1948.—Dr. EDITH SUMMERSKILL replied: In 1948, 3792 applicants were examined by the Silicosis Medical Board under the Workmen's Compensation Acts, of whom 1509 were certified. The corresponding figures for 1949 were 1531 and 520. In addition in 1948 there were 3992 applications for benefit for pneumoconiosis under the Industrial Injuries Act, of whom 1687 were found to have the disease. For 1949 the figures were 12,764 and 3612.

Hearing-aids

In answer to a question Mr. BEVAN stated that last month the average weekly output of 'Medresco' hearing-aids was 1500.

Liverpool Doctor's Patients

Mr. K. PUGH THOMPSON asked the Minister of Health if his attention had been drawn to the disquiet and distress caused to many patients of Dr. W. F. Jones of Walton, Liverpool, following their summary removal from his list; and if he would issue instructions to the executive council that their position was to be reviewed before any final decision was made.—Mr. BEVAN replied: This doctor had over 6800 patients on his list, the number agreed with the profession as the maximum which normally a single-handed doctor can adequately care for being 4000. He did not himself take steps to meet the situation and in the circumstances the action taken by the executive council seems to me to have been reasonable.

Extraction Rate of Flour

Dr. BARNETT STROSS asked the Minister of Food what was the degree of extraction of flour from wheat in use today for the making of normal bread; the degree of extraction in 1938; and what were the contents in each case, of protein, fat, iron, calcium, phosphorous and vitamins, including carotene.—Mr. STANLEY EVANS replied: The extraction rate of flour used in 1938 varied, but 70% was the most usual; the present extraction rate is 85%. The average composition of flour of 70% and 85% extraction rates is as follows:

	70% extraction per oz.	*85% extraction per oz.*
Protein	3·1 g.	3·3 g.
Fat	0·3 g.	0·5 g.
Iron	0·28 mg.	0·6 mg.
Calcium	4·5 mg.	46 mg.*
Phosphorous	26 mg.	54 mg.
Vitamin B_1 (aneurin)	0·021 mg.	0·082 mg.
Riboflavin	0·017 mg.	0·037 mg.
Nicotinic acid	0·23 mg.	0·57 mg.

* Includes calcium added as creta preparata.

Flour contains a negligible quantity of vitamin A (or carotene) and no vitamins C or D.

Health in the African Dependencies

Mr. SIDNEY MARSHALL asked the Secretary of State for the Colonies what had been done to implement the recommendation of the Kenya Development Subcommittee on Health in regard to the setting up of a royal commission to inquire into the health of all the peoples of H.M. dependencies in Africa.—Mr. JAMES GRIFFITHS replied: The recommendation of this subcommittee was also the subject of an approach in 1947 by the Kenya branch of the British Medical Association who asked that the royal commission should in addition cover population questions. These proposals were considered by my predecessor who, in 1949, decided that as far as the East African Territories were concerned the appointment of a royal commission on population would be inappropriate.

Further statistical information is at present in the course of preparation and the position will be reviewed again when it becomes available. Innumerable efforts are being made by the governments of the British Colonial Territories in Africa to improve the health of the people and it is considered that an official inquiry of the kind suggested could not be of real value until a stage has been reached at which it will be possible to draw conclusions from the results of these efforts. I am not therefore prepared to recommend the appointment of a royal commission at present.

Obituary

JOHN CLARENCE WEBSTER

C.M.G., M.D. EDIN., LL.D., F.R.C.P.E.

Dr. Clarence Webster, who died at Shediac, New Brunswick, on March 16 at the age of 86, was a graduate of Edinburgh who had achieved distinction as a gynæcologist in the United States and as a historian in Canada.

Of Scottish and Yorkshire stock, he was born at Shediac, where his father was a prosperous storekeeper, and graduated B.A. at Mt. Allison University in New Brunswick when he was 19. He persuaded his father in 1883 to send him to Edinburgh. After a brilliant career as a student he graduated M.B. with honours in 1888. From postgraduate study at Leipzig and Berlin he returned to Edinburgh to take his M.D. in 1891, receiving the gold medal for his thesis. In 1893 he became F.R.C.P.E.

In 1890 Sir Alexander Simpson, the professor of midwifery, appointed him as his assistant. He held this post for six years and he seemed marked out as Simpson's successor. But severe attacks of laryngitis and bronchitis impelled him to leave the damp climate of Edinburgh, and in 1896 he accepted an appointment in Montreal as lecturer in gynæcology at McGill University.

Three years later he migrated to Chicago to take the chair of obstetrics and gynæcology at the Rush Medical College. There he spent twenty strenuous years in teaching and in an extensive private practice. He also served as chief gynæcologist at the Presbyterian Hospital and the Central Free Dispensary, yet he found time to write freely. *The Practice of Obstetrics* (1899), *Human Placentation* (1901), *A Textbook of Obstetrics* (1903), and *A Textbook on Diseases of Women* (1907) were all produced during his early years in Chicago. But by 1919 the strain of his busy life had begun to affect his health, and, since his standard fee of $1000 for each accouchement had enabled him to accumulate a comfortable fortune, he decided to retire from all his medical work. The University of Illinois made him an emeritus professor of obstetrics and gynæcology in 1942.

It was open to him to live in leisured ease in a pleasant climate like that of California or British Columbia, but he elected to dwell among his own people at Shediac, where he had built himself a house at the mouth of the Scugog River. He threw himself actively into the life of his native town, joined the governing body of Dalhousie University, and took a keen interest in local education and in Canadian public affairs. From his boyhood history had interested him and he now became an assiduous collector of Canadiana—pictures, books, maps, and documents. Later he embarked on original research into Canadian history, and in successive winters he visited libraries, archives. and museums in Canada, the United States, Britain, and France, gathering a large store of interesting material relating to the early history of Canada. Writing never came easily to him, but in his private autobiographical memoir, *The Crowded Years* (1943) he was able to list some 50 short books and monographs on historical subjects. His reputation as an authority on the history of Canada's maritime provinces led to his appointment as a member of the Historic Sites and Monuments Board of Canada, in which he served as chairman for six years. He was appointed C.M.G. in 1935. He also held honorary degrees of the universities of Edinburgh, New Brunswick, Dalhousie, Mt. Allison, and Cincinnati.

A friend writes: "Clarence Webster was a singularly handsome man, who remained slim and straight and retained in an amazing degree the élan of youth till the end of his long life. He had great personal charm and he was the best of company, for he was a fine talker with a wide range of interests. Though he did not suffer fools gladly and was accused by some of having too autocratic a temper, there was no more respected or widely beloved figure not merely in Shediac but in the whole province of New Brunswick."

In 1899 he married Miss Alice Lusk of New York, who survives him with a son who is a distinguished physicist. Their elder son was killed in a flying accident in 1931 and their only daughter, who had married a French artist, died in a German internment camp in 1944.

GEORGE EWART MARTIN

M.A., M.B. EDIN., F.R.C.S.E.

Dr. G. Ewart Martin, senior ear, nose, and throat surgeon to Edinburgh Royal Infirmary and senior lecturer on otolaryngology at Edinburgh University, died on March 27, at the age of 61. Though he was no narrow specialist, and his wise counsel on general medical affairs was welcome in many important quarters, Ewart Martin was best known as an endoscopist. He was the leading exponent of broncho-œsophagology in Britain and, indeed in Europe.

His old chief, Logan Turner of Edinburgh, who was the first bronchoscopist in Britain, persuaded Ewart Martin in 1920 to take a postgraduate course at Philadelphia under Prof. Chevalier Jackson. Ewart Martin was the first British postgraduate to do so; he returned to Edinburgh full of enthusiasm, and in after years he never found any necessity to depart from Jackson's principles or from the design of his instruments. By the middle of 1947 he had personal records of 4040 endoscopic cases, and he was the first to treat bronchiectasis by bronchoscopic lavage, not, as was sometimes assumed, as a cure, but because he believed that lobectomy or pneumonectomy should not be attempted until the rest of the chest was entirely clear. He was invited to address the section of otolaryngology at the Centenary Meeting of the American Medical Association in 1947, and to give the Semon lecture at the University of London in 1948; on each occasion he spoke on broncho-œsophagology, regretting that in many centres it appeared to be passing from the hands of the laryngologist into the hands of the thoracic surgeon, and pointing out that the foreign-body emergencies still came to the ear, nose and throat departments and that the teaching of the subject must remain with the laryngologists.

A native of Inverness, he was educated at Inverness Royal Academy and Edinburgh University, where he graduated M.A. in 1910 and M.B. in 1913. In 1914 he went to France as a surgical specialist in a casualty-clearing station, and after the war he became clinical assistant in the ear, nose, and throat department of the Edinburgh Royal Infirmary, taking the F.R.C.S.E. in 1920. Besides his teaching appointments, Ewart Martin held consulting appointments at Bangour Hospital, Kirkcaldy Hospital, and Kelso Hospital. He was also adviser in otolaryngology to the Department of Health for Scotland, consultant aural surgeon to the Ministry of Pensions, a member of various committees of the Medical Research Council, a member of the faculty of medicine of Edinburgh University, and a member of the council of the Royal College of Surgeons of Edinburgh. He had been president of the Scottish Otological and Laryngological Society, and president of the section of laryngology of the Royal Society of Medicine.

A colleague writes: "Ewart Martin was an unmistakable Scot, good-natured and with a boyish sense of humour, a non-smoker and teetotaller, an elder of West St. George's Church, an old-fashioned Liberal, apt to be a little ruffled if he thought Scottish interests in any subject were being neglected or pushed aside. He was excellent in committee, where his practical common sense was always valued, though he held his opinions firmly and on occasion his comment could be blunt. A sound clinician and a dextrous operator, he had no exaggerated ideas about the amount of otolaryngology that medical students could absorb in three months and he was perhaps at his best with young postgraduates, to whom he was a constant stimulus as well as a kind friend and adviser. The consultant otologists to the Army and to the R.A.F. have each asked that it should be put on record that both Services owed a great deal to Ewart

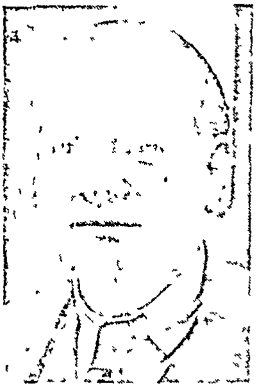
Martin for his friendly advice and for his training of many young specialists in his department at Edinburgh."

He is survived by a widow, two young married daughters, and two sons.

HECTOR BRUCE MACKENZIE

M.B. EDIN.

Dr. Bruce Mackenzie, who died in Auckland on March 13 at the age of 57, was the son of the late Sir Thomas Mackenzie, prime minister of New Zealand in 1912, and a brother of the late Kenneth Mackenzie, surgeon, of Auckland, who died in 1942.



[*New Zealand Herald*

Bruce Mackenzie graduated at the University of Edinburgh in 1918, and after serving as a medical officer at the end of the first world war returned to New Zealand. In 1921 he started in practice in Auckland as a radiologist, and he steadily built up a large practice on both the diagnostic and the therapeutic sides. For many years he was treasurer of the Auckland branch of the British Medical Association, and later he became its president. Our New Zealand correspondent writes: "Mackenzie's work was always thoughtful, thorough, and painstaking, and he was known and loved by a wide circle of colleagues and patients. He had a quiet charm and dignity of manner, and was a happy man to whom nothing was too great a trouble in obliging a patient or colleague. He served the Auckland Hospital in a part-time capacity from 1923 to his death. His sound ideas and practice played no small part in raising the status of radiology as a specialty in New Zealand. He was a keen chess player, and an outstanding exponent of contract bridge."

He is survived by his widow, two daughters, and one son who is a final-year medical student.

ARTHUR BRITON SMALLMAN

C.B.E., D.S.O., M.D. MANC., D.P.H.

Lieut.-Colonel A. B. Smallman, who died on March 4, was the first representative of the Ministry of Health on the National Radium Commission when it was set up in 1929, and he served in this capacity until 1935. After his retirement from the Ministry in 1938 he acted as liaison officer between the two bodies. He combined this work with that of secretary of the commission, at first jointly with G. F. Stebbing and later (1939–41) alone.

Born in 1873, he was educated at Manchester Grammar School and at the Victoria University, where he graduated M.B. with honours in 1897. After serving as a civil surgeon in the South African war he joined the Royal Army Medical Corps in 1902. A year later he took his M.B. Lond and the D.P.H. During the Balkan war he saw service with the Turkish forces, and in the 1914–18 war he was D.A.D.M.S. with the 1st Division in France, and later at G.H.Q., afterwards becoming D.A.D.G. and A.D.G., Army Medical Services. For this work he was five times mentioned in despatches and appointed C.B.E. and D.S.O. He retired in 1920 and joined the staff of the Ministry of Health.

"Smallman's all-round knowledge of cancer was invaluable to the Radium Commission; he had done much at the Ministry to lay foundations on which the commission was later to build. In particular, the statistical committee, of which he was a member until its dissolution in 1948, made constant calls on his knowledge of cancer statistics in its efforts to initiate and improve a national system of cancer records. Throughout the years when he represented the Ministry of Health on the commission his scrupulous fairness and lack of bias were greatly appreciated by his colleagues."

Colonel Smallman married, in 1916, Alice Florence, second daughter of the late Hon. R. G. Duncan, and they had two sons.

Notes and News

ROYAL AUSTRALASIAN COLLEGE OF PHYSICIANS

THE twelfth annual meeting of the college, and the first to be held in New Zealand, was held in fine summer weather, at Auckland Hospital and Auckland University College from March 21 to 23. Members from various States in Australia and the south of New Zealand attended, and a full programme of clinical and scientific work was discussed. Examinations were held before the meeting and six new members were admitted, three being presented at the public meeting in the college hall. This was held in full academic dress and presented a brilliant spectacle. Dr. Holmes à Court, of Sydney, the president, gave an address, and Dr. E. M. Blaiklock, professor of classics at Auckland University College, described Some Medical Personalities of Ancient Times.

MISUSE OF STREPTOMYCIN

THE World Health Organisation has issued a warning against unrestricted distribution and indiscriminate use of streptomycin, in a move to avoid the emergence of streptomycin-resistant strains of tubercle bacilli. In a letter to all member states, Dr. Brock Chisholm, director-general of the Organisation, calls attention to the warnings issued by the executive board on the basis of reports produced by the expert committee on tuberculosis. The warning against abuse of streptomycin points out that: (1) despite the reduced toxicity of new forms of streptomycin, the drug must still be regarded as having danger; (2) precise knowledge as to its clinical indications, especially in pulmonary tuberculosis, is still lacking; and (3) the attention of the public may be focused on this drug to an extent out of all proportion to its value in the total campaign against tuberculosis. W.H.O. is now providing a consultative service to a number of countries in Europe—Austria, Czechoslovakia, Greece, Italy, Poland, and Yugoslavia—which are receiving supplies of the drug from UNICEF.

MOTH DERMATITIS

THE latest report on moth dermatitis comes from Norway. On Feb. 28, 1949, Bergen City Hospital received a wireless message from a 16,000 ton Norwegian tanker in the Atlantic asking for advice: "If possible wire medical advice for so-called Caripito itch caused by dust from the wings of moths. The whole crew attacked. The rash like that from primula. Violent itching, no fever. Have given remedies for itch, but result negative." From Bergen, Dr. J. Boe[1] prescribed ephedrine tablets three or four times a day and frequent washing with a weak solution of ammonia. A couple of days later the captain reported that all his patients were better. Later it was learned that 41 of the crew of 44 were attacked by a papular rash which became vesicular, and in some cases covered the whole body. The itching was terrible, and in the worst cases the resulting insomnia did not respond to soporifics. Water on the rash made matters worse. On an earlier visit to Caripito, a Venezuelan port, the tanker had been warned by the harbour master to beware of dust from the wings of moths; and when last in Caripito, during the rainy season, the ship had been visited by swarms of moths. Dr. Boe heard from Venezuela that the offending moth belongs to the family *Saturnidæ*, genus *Hylesia*. In 1947 a migrating swarm of female *Hylesia* was responsible for a spectacular outbreak on board an oil tanker off the coast of Venezuela.[2]

University of London

On Tuesday, April 25, at 5 P.M., at Guy's Hospital Medical School, London, S.E.1, Prof. G. Westin (Stockholm) will give a lecture on Histological Aspects of Gingival Disease.

Prof. R. W. Russell, PH.D., has been appointed to the chair of psychology at University College from Oct. 1.

University of Aberdeen

On March 29, the following degrees were conferred:

D.Sc.—G. A. G. Mitchell.

M.D.—K. B. Fraser (with honours).

M.B., Ch.B.—T. P. G. Allison, Miriam Blank, John Breeze, J. M. Craig, Eileen Davis, G. B. Farquharson, James Geddes, J. L. Hardie, Duncan McNicol, T. F. P. Pimley, M. R. Pinnock, Donald Ross, P. M. Sammon, J. W. T. Shepherd, A. J. Tulloch, M. J. A. Watson.

---

1. *Nord. Med.* Feb. 17, 303.
2. See *Lancet*, 1949, i, 165.

Royal College of Physicians of Ireland

On March 3 Haldane Graham Nelson was admitted to the membership.

On March 31 the following were admitted to the licentiateship:

P. J. Briggs, M. L. Brosnan, O. G. Corrigan, Ellen P. Doyle, D. P. Harris, Julianne Horgan, Noel Hurley, Anthony Loftus, Anne M. Maguire, Margaret M. Murphy, Joyce M. McCall, P. J. McCormack, Alice T. McGlinchey, Sybil B. Orgel, M. F. Plunket, Joseph Vilensky, J. J. Walsh, Gladys I. Wilson.

Royal College of *Surgeons in Ireland*

On March 31 the fellowship was conferred on D. F. V. Lane, C. C. D. Martin, and E. A. McVerry.

Royal Faculty of Physicians and Surgeons of Glasgow

At a meeting of the faculty held on April 3, with Dr. W. R. Snodgrass, the president, in the chair, the following were admitted fellows of faculty:

B. R. Hillis, Kashi Ram Mahajan, Ravindra Vasant Rele, I. D. Riley, J. A. Simpson, G. A. Walker, *qua* physician; R. R. Gilfillan, J. H. Miller, *qua* surgeon.

Association of Surgeons of Great Britain and Ireland

The annual meeting of the association will be held at the Royal College of [illegible] W.C.2, on May 4, 5, a[illegible] ussions on Gravitationa[illegible] Boyd); the Gastric Bl[illegible] Anticoagulants in Surgery (Prof. R. M. Janes); and the Physiology of the Alimentary Tract following Operation for Simple Peptic Ulcer (Prof. Charles Wells).

Royal College of Obstetricians and Gynæcologists

An appeal was launched last week for £400,000 to further the work of this college. It is proposed to devote £200,000 to building, £150,000 to research and the general funds, and £50,000 to establishing a Commonwealth travelling professorship. The president of the appeal is Lieutenant-General Sir Ronald Weeks.

Society of Apothecaries of London

At a meeting of the court of assistants on March 28, with Mr. Duncan Fitzwilliams, the master, in the chair, it was announced that the Minister of Town and Country Planning had included the society's property in the final list of buildings of special architectural or historic interest.

Ten postgraduate lectures on Modern Methods of Diagnosis and Treatment are to be held from Dec. 4 to 8.

A. W. Kendall, examiner, was clothed by the master with the livery of the society. The following were admitted to the freedom of the society by redemption:

H. L. Shepherd, A. D. Briscoe, R. L. Jillett, B. G. Parsons-Smith, G. E. W. Wolstenholme, Victor Dix, G. I. M. Swyer.

The following diplomas were granted:

D.I.H.—M. M. Abdel-Latif, D. E. Barton, R. E. W. Fisher, E. A. W. Marien, R. Murray, G. H. G. Southwell-Sander, J. Watkins-Pitchford.

L.M.S.S.A.—M. A. Abraham, S. N. Shenai, M. E. M. Grasse, J. C. Anderson, L. I. Norman, D. H. Le Clus, A. C. De Beer-Eksteen, C. R. Lynn.

Congress on Industrial Medicine

The tenth International Congress on Industrial Medicine will be held at Lisbon from Sept. 9 to 15, 1951, under the presidency of Dr. Alex Ribeiro da Cunha. Further information may be had from the Service de Relations Internationales, Institut National du Travail et de la Prévoyance, Praça do Comércio, Lisbon, Portugal.

Conference of the Social Services

The theme of the British National Conference on Social Work, which is to be held at Harrogate from April 19 to 23, is to be the respective rôles of statutory authorities and voluntary organisations. This will be studied through commissions on child welfare; social aspects of health, including mental health; rehabilitation and the care of the handicapped; social adjustment, including family counselling, problem families, and juvenile delinquency; community services, including recreation and informal education; and social aspects of town and country planning and of housing. The speakers will include Prof. J. C. Spence and Dr. Alice Stewart. Dr. Albertine Winner is to be chairman of the commission on social aspects of health. Further particulars may be had from Miss M. L. Harford, 26, Bedford Square, London, W.C.1.

International Congress on Asthma

The second International Congress on Asthma will be held at Mont-Dore on June 3, 4, and 5, under the presidency of Prof. Pasteur Vallery-Radot. Further information may be had from Dr. J. Galup, 59, rue Bonaparte, Paris VI.

Research Defence Society

On Friday, April 21, at 5.30 P.M., at 11, Chandos Street, London, W.1, Mr. A. L. Bacharach, F.R.I.C., will speak on the Production and Care of Laboratory Animal Stocks.

R.A.F. Reserves Club

This club, of which Sir Archibald McIndoe is a vice-president, would welcome as members doctors who are ex-R.A.F. officers. Further details may be had from the chairman of the membership committee, R.A.F. Reserves Club, 38, Hill Street, London, W.1.

Claims to Sickness Benefit

In England and Wales new claims to sickness benefit under the National Insurance Act during the weeks ended March 7, 14, 21, and 28 numbered 181,200, 188,600, 188,400, and 165,700; during the month the weekly average was 181,000. The weekly averages from March, 1949, to February of this year were: 185,200, 114,400, 97,700, 83,500, 78,600, 88,800, 100,900, 119,100, 136,200, 96,700, 154,900, and 178,100.

Employment of Nurses on Unauthorised Conditions

Hospital authorities have been advised that after April 30 no nurse or midwife may be employed in any hospital in the National Health Service except at the rates of remuneration, and on the conditions of service, authorised by the Minister of Health in accordance with recommendations of the Nurses and Midwives Salaries Committees or agreements reached by the Nurses and Midwives Whitley Council.

Inquests in London

At a meeting last Tuesday the London County Council received a report showing that 2089 inquests were held in the county during 1949. Altogether 1113 persons met their death by accident; 24 deaths resulted from injury and 30 from drowning; 14 deaths were found to be caused by want of attention at birth; and 13 deaths were caused by excessive drinking. Suicides numbered 462 (152 over the age of 60 years). A verdict of "death from natural causes" was returned in 314 cases.

Royal Society

On Thursday, April 27, Prof. H. D. Kay will describe the functions and scope of the National Institute for Research in Dairying, and on Thursday, May 18, Mr. F. Kidd the functions and scope of the Food Investigation Board. On Thursday, June 15, Dr. F. M. Burnet will deliver a Croonian lecture on the Interaction of Virus and Cell-surface. On Thursday, June 29, Prof. J. Z. Young will give the Ferrier lecture on Growth and Plasticity in the Nervous System. All the lectures will be held at the society's rooms, Burlington House, Piccadilly, London, W.1, at 4.30 P.M.

Mental Health Congress *in Eire*

A congress on mental health is to be held at the Hospital of St. John of God, Stillorgan, co. Dublin, on April 17, 18, and 19, in conjunction with the commemoration of the fourth centenary of the death of St. John of God. Dr. Alfred Torrie is to deliver the opening address on the Individual's Responsibility for Mental Health. Other speakers will include Dr. Leslie Hilliard, Dr. Richard Lavelle, Dr. F. L. McLaughlin, Dr. P. F. O'Brien, Dr. A. J. Devlin, Dr. M. M. Walsh, and Dr. Mary Mulvany.

Science and Food Rationing

A conference on this subject is to be held on Friday and Saturday, April 28 and 29, at University College, London. The aim of the conference is "to bring a greater sense of realism to the teaching of biology in relation to nutrition in schools, and to provide members of the general public with a better scientific understanding of food." There will be sessions on Science and Food Rationing, Food and Mankind, the Nutritive Value of the Average Family Diet, and Food Supplies—Future Prospects. The speakers will include Professor John Yudkin, M.D. Tickets for the conference can be had from the British Social Hygiene Council, Tavistock House North, Tavistock Square, W.C.1.

Royal Visit to Mill Hill

On Friday, May 5, the King, who will be accompanied by the Queen, will open the new building of the National Institute for Medical Research at Mill Hill.

Robert Jones Travelling Fellowship

The first award of this travelling research fellowship will shortly be made from the Robert Jones National Memorial Fund. Further particulars will be found in our advertisement columns.

New Hospital for Chronic Sick

The Wilderness Hospital at Mitcheldean, Glos, which was formerly an isolation or smallpox hospital, is now to be used for the accommodation of the chronic sick. There will be accommodation for 30 cases. The hospital is now to be known as The Mitcheldean Hospital.

National Marriage Guidance Council

The annual conference of the council will be held at Rustington Lido, near Littlehampton, from May 6 to 13. Further particulars may be had from the secretary of the council, 78, Duke Street, London, W.1.

Modern Microscopy

The Royal Microscopical Society and the Electron Microscopy Group of the Institute of Physics are holding an international convention on this topic at King's College Medical School, Newcastle upon Tyne, from April 18 to 21. The secretary of the convention is Dr. A. E. J. Vickers, Wynnstay, Millfield Road, Whickham, Newcastle upon Tyne.

International Conference of Social Work

A meeting of social workers and others engaged in social service will be held in Paris from July 23 to 28 to discuss *Social Work in 1950: its Boundaries and its Content.* Leaflets giving further information may be had from the Secretary, British National Committee, National Council of Social Service, 26, Bedford Square, London, W.C.1.

International Conference on Geriatrics

The first international conference of gerontological societies will be held in Liége, from July 9 to 12. Each society may send up to five delegates, and the delegates of the British Society for Research on Ageing are Prof. E. C. Dodds, F.R.S., (chairman of the delegation), Prof. J. B. Duguid, Prof. R. E. Tunbridge, Dr. Macdonald Critchley, and Dr. V. Korenchevsky. In addition to the presentation and discussion of the results of gerontological research, it is the purpose of this conference to establish an International Union of Gerontological Societies and to promote the financing of research in this subject throughout the world. Further information may be had from Prof. L. Brull, chairman of the organising committee, Hôpital Bavière, Liége, Belgium.

Births, Marriages, and Deaths

BIRTHS

CAYTON.—On March 27, the wife of Dr. H. R. Cayton—a son.

COHEN.—On April 2, at Preston, the wife of Dr. S. Cohen—a daughter.

DAVIES.—On March 29, at Abergavenny, the wife of Dr. T. G. Davies—a daughter.

DOWLING.—On April 4, at Bristol, the wife of Dr. Alexander Dowling—a daughter.

ELLIOTT.—On April, 2 at Oxford, the wife of Dr. John Elliott—a son.

FORBES.—On March 31, at Oxford, the wife of Dr. H. A. W. Forbes—a daughter.

GOODWIN.—On April 4, in Manchester, the wife of Mr. M. A. Goodwin, F.R.C.S.E.—a daughter.

GOW.—On March 28, at Crowborough, the wife of Dr. A. H. Ferguson Gow—twin sons.

MILNES.—On March 24, in London, the wife of Dr. J. N. Milnes—a daughter.

MORRIS.—On March 29, in London, the wife of Dr. David Morris—a son.

SELLICK.—On March 30, in London, the wife of Dr. B. A. Sellick—a son.

MARRIAGES

BROWN—PENNELL.—On April 1, at Seal, Kent, Kenyon Carnarvon Brown, M.B., to Sylvia Doris Pennell.

SUTHERLAND—CARLILE.—On April 1, at Burton-on-Trent, Charles Morrison Sutherland, M.B., to Mary Carlile, M.R.C.S.

DEATHS

BRADFORD.—On April 3, at Bridport, John Bradford, B.A., M.B. Camb.

FLEMING.—On April 1, at Robroyston, Glasgow, Janet Haddow Allan Fleming, L.R.C.P.E.

GRANT.—On March 24, at Cerrig-y-Druidion, North Wales, Lewis Grant, M.A. Aberd., M.D. Edin.

RILEY.—On April 3, at Broadstairs, Ronald Riley, B.A. Camb., M.R.C.S.

Diary of the Week

APRIL 16 TO 22

Monday, 17th

MAIDA VALE HOSPITAL, W.9
4.30 P.M. Dr. Russell Brain, P.R.C.P.: Opening address of the spring session.

HUNTERIAN SOCIETY
7.30 P.M. (Talbot Restaurant, 64, London Wall, E.C.2.) Mr. Peter Casson: Hypnotism.

Tuesday, 18th

SOCIETY FOR THE STUDY OF ADDICTION
4 P.M. (11, Chandos Street, W.1.) Dr. A. Spencer Paterson: Modern Techniques for the Treatment of Acute and Prolonged Alcoholism.

UNIVERSITY OF EDINBURGH
5 P.M. (Physiology lecture-theatre, University New Buildings, Teviot Place.) Dr. Douglas Guthrie: Science of Retrospection. (First of a series of lectures on A Retrospect of Medicine and Science.)

Wednesday, 19th

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE, 28, Portland Place, W.1
3.30 P.M. Dr. G. Scott Williamson: The Pioneer Health Centre.

Thursday, 20th

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL, S.W.1
4.30 P.M. Dr. Desmond Curran: Psychiatry lecture-demonstration.

SOCIETY OF MEDICAL OFFICERS OF HEALTH
5.30 P.M. (B.M.A. House, Tavistock Square, W.C.1.) Dr. Joan Taylor: Salmonella Infections in Humans and Animals.

HONYMAN GILLESPIE LECTURE
5 P.M. (Anatomy Theatre, University New Buildings, Teviot Place, Edinburgh.) Prof. L. S. P. Davidson: Physiological and Clinical Effects of the Pituitary Adrenocorticotrophic Hormone and the Adrenal Cortical Hormones.

Friday, 21st

FACULTY OF RADIOLOGISTS
2.15 P.M. *Diagnosis Section.* (Royal College of Surgeons, Lincoln's Inn Fields, W.C.2.) Dr. J. C. H. Mackenzie: Chest X Rays in Infectious Diseases. Dr. J. D. Dow: Venography in Varicose and Post-phlebitic Ulceration. Dr. E. Hanson: [illegible]

WEST LONDON MEDIC [illegible]
8 P.M. (Hammersm [illegible] oad, W.12.) *Clinical* meeting.

MIDDLESEX COUNTY MEDICAL SOCIETY
3 P.M. (Central Middlesex Hospital, Acton Lane, N.W.10.) [illegible]

ROYAL [illegible] 16, Princes Gate, S.W.7
7 P.M. [illegible] *B. Brain*, F.R.P.S.: Dental Microscopy and its Photography.

Appointments

*CHARRETT, M. A., M.R.C.S., D.P.H.: M.O.H., Slough, and area M.O., South Bucks.

CRAN, EVA, M.A., M.B. Aberd., D.P.H.: asst. divisional M.O., public-health department, London County Council.

MACKENZIE, K. G. F., M.A., M.B. Camb., F.R.C.S.: consultant asst. surgeon, North West Durham group of hospitals.

* Amended notice.

Appointed Factory Doctors:

CROMARTY, J. W., M.B. Edin.: Stromness district, Orkney.
HAMILTON, J. N., M.B. Glasg.: Lovenwick district, Shetland.
KERR, W. A., M.B. Glasg.: Fleetwood district, Lancs.

CORRIGENDA.—*Fig.* 4 in Professor Stammers's article (*Lancet*, April 1, p. 604) was reproduced by permission of *Surgery, Gynecology, and Obstetrics.*

Diagnosis of diabetes insipidus.—Our report (April 1) of this discussion by the endocrinology section of the Royal Society of Medicine did not make clear the test devised by Dr. A. A. G. Lewis and Dr. T. M. Chalmers.

In this test the antidiuretic response to nicotine is calibrated in terms of the milli-units of pitressin needed to produce an inhibition of diuresis of the same duration. Every subject is given a water load of 1 litre and empties his bladder every 10 minutes. Arbitrarily, the time of inhibition is taken from the end of the infusion or inhalation to the time when the urine flow returns to the level of 10 ml. a minute. This procedure is then repeated, substituting a measured intravenous dose of pitressin for the nicotine. In any one subject there is a linear relation between the duration of inhibition after pitressin and the logarithm of the dose; and by giving different doses of pitressin on two occasions, the dose-response curve can be constructed and the antidiuretic response to nicotine evaluated in terms of milli-units of pitressin. Subjects with a normal supraopticohypophyseal system give responses greater than 100 milli-units of pitressin, provided enough nicotine is given to produce definite malaise. In subjects with a damaged supraopticohypophyseal system the response is less than 10 milli-units of pitressin.

THE OPEN WOUND IN TRAUMA

PETER ESSEX-LOPRESTI
F.R.C.S.E., D.A.
ASSISTANT SURGEON, BIRMINGHAM ACCIDENT HOSPITAL

I. The Case for Early Closure

AT the beginning of this century, following the work of Friedrich in 1898 on the early excision of recent wounds, surgeons began to reduce the high incidence of serious infection associated with open wounds and fractures by primary excision and closure. Conditions in the early years of the first world war, however, were such that primary closure was not attempted, and the dire consequences of grave infection were again evident until surgeons began to treat the wounds by excision and delayed primary closure.

The success of this technique in the last two years of the war was largely forgotten in the inter-war years, and the practice of leaving wounds open was encouraged by the publication in 1939 of Trueta's work on the closed-plaster treatment applied to open fractures. His advice perhaps obscured the greater value of complete skin cover provided at the earliest possible moment. As Cleveland (1946) points out:

> "At the outset of this war, our surgeons were dominated by the closed-plaster technique of treatment of compound fractures. This invites infection of bone and soft tissue and healing ensues slowly by second intention, with massive granulations which developed into scar tissue. . . . So firmly ingrained was the idea of closed-plaster technique, that it was not a little difficult to persuade the medical officers at first to attempt closure of these compound fractures."

Trueta (1949) now says: "since penicillin came to the help of the surgeon, no well excised wound ought to be left open for more than 8–10 days for fear of sepsis after its closure. And it is the duty of the surgeon to effect this in every case." There is still, however, considerable confusion.

In this paper I shall recommend primary closure of the open wound in civilian accident surgery, believing that the dangers of added infection incurred by leaving a wound open are far more serious and far-reaching than those of primary closure. I shall show that added infection of an open wound, such as a burn, can be prevented by an elaborate technique, and shall suggest that if, for technical reasons, a wound cannot be closed at once, this technique must be applied until closure can be achieved by skin.

There is little in this paper that is new, but the results of much recent work have not been fully applied and the practice of immediate closure is still not universal. Böhler (1935), for over twenty years, has taught the principles which will be discussed here, and produced in 1926 results which have seldom been bettered, in spite of the additional security afforded by modern bacteriostatic agents. Gissane (1939) has advocated and practised these principles in this country for over ten years with equally good results.

There is no need to differentiate between the treatment of an open fracture and an open wound of soft tissues, for one is merely an extension of the other. The argument for early closure applies to any deep tissue exposed to the air. It is true that the effects of added infection are more serious where a fracture complicates the open wound, but the bacteriological and clinical evidence is as valid for the open wound as it is for the open fracture. From what follows it will be clear that the proper treatment of open wounds is a time-consuming matter, and for this reason adequate space, theatre, and staff are essential in every casualty department. No-one, for example, can treat an open fracture of a long bone properly in much under one hour of theatre time, and it may well take two or more hours. It is an emergency operation which cannot wait till the end of a list of strangulated herniæ, appendicectomies, and the like in the general theatre.

CONTAMINATION

Generations of surgeons have tried to prevent putrefaction and gangrene after war wounds, and since 1879, when Pasteur published his work on micro-organisms, it has been assumed that all open wounds caused by trauma are contaminated with pathogenic organisms. In his book Trueta (1943) contributes no evidence that this is so; but his technique of wound surgery is apparently based on a belief in such contamination, and he ranks the provision of drainage as one of the principles in his five-point programme—namely, (1) prompt surgical treatment, (2) cleansing of the wound, (3) excision of the wound, (4) provision of drainage, and (5) immobilisation in a plaster-of-paris cast. Though I shall produce evidence that in fact open wounds are *not* commonly contaminated by dangerous organisms at the time of injury, this does not mean that I am questioning all Trueta's five points. Prompt surgical treatment, cleansing, and excision are vital parts of the treatment: moreover, where the open wound is large or complicated by fractures, plaster immobilisation is invaluable, and the meticulous care and attention to detail stressed by Böhler and Trueta are essential to success.

If, however, a wound is not initially contaminated by pyogenic organisms, the provision of drainage is not necessary, and it may even be harmful, for infection may enter through the open wound. Furthermore, if infection is present, as Sir Almroth Wright proved, "so long as the wound remains open the infection is never extinguished, and washing and dressing impose only a temporary restriction upon bacterial growth." By a beautiful series of simple experiments Wright showed that the leucocytes can rapidly sterilise a wound when they are concentrated by apposition of its walls and by the elimination of dead spaces. "The proper principle when dealing with a wholesome wound is to close in order to sterilise, instead of using antiseptics with a view to closing."

INFECTION

It has been taught that contamination becomes infection through the multiplication of pyogenic organisms and their invasion of the tissues. The fact that infection sooner or later occurs in almost every case of traumatic wound left open has been adduced as evidence of this process, and variation in the interval before its onset has been attributed to variation in the virulence of the organisms or the immunity of the tissues or to delayed growth in the species.

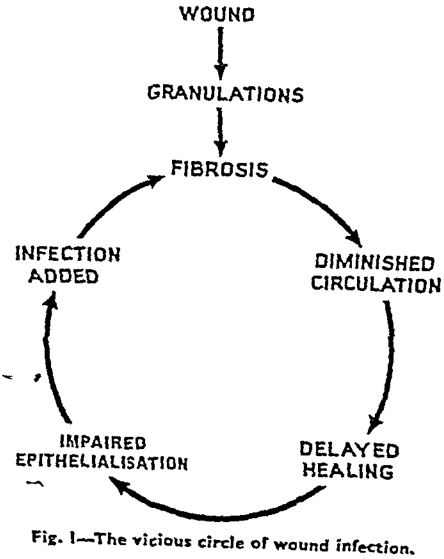


Fig. 1—The vicious circle of wound infection.

There is no doubt that infection is the most dreaded complication of any open wound. Not only may it threaten life and limb but it always delays healing and increases fibrosis. The vicious circle of wound infection is well known: Marquis Converse (1941) and others have described it many times (fig. 1). Granulation tissue becomes fibrous tissue, which contracts and cuts down the blood-supply: poor vascularity delays epithelialisation and permits added infection through the ulcer, which in turn produces more granulation tissue, fibrosis, and so on. As Colebrook, Duncan, and Ross (1948) put it, " the wound did not heal, because it was infected; and it remained infected, because it did not heal."

Fibrosis is the enemy of function. Any wound which is left to " heal from the bottom " or which has become infected, heals by second intention—i.e., by the formation of granulation tissue, fibrosis, and epithelialisation. Late split-skin grafting over granulation tissue is open to the same objection—fibrosis and contracture—and granulation tissue and fibrous tissue should be removed where possible before grafting. If we want full function and a soft supple scar, we must avoid fibrosis; and to achieve this the wound must be made to heal by first intention and without infection.

THE EVIDENCE FROM WOUND BACTERIOLOGY ON ADMISSION

What is the evidence for the statement that wounds are not commonly contaminated by pathogenic organisms at the time of injury? Colebrook, Duncan, and Ross (1948) showed in the burns unit of the Birmingham Accident Hospital that over 90% of 734 recent burns and scalds were completely free from pathogens on admission; indeed, if we exclude cases burned more than a few hours previously, the proportion is almost 100%. Many workers have demonstrated that about four-fifths of all recent wounds are free from pathogenic organisms (table I) and that in most of the others a few colonies of *Staphylococcus aureus* constitute the only danger—these being mainly in the 10–20% of people who are normally skin carriers of this organism (Miles et al. 1944, Williams and Miles 1945, Williams 1946). Admittedly, bacteria can be found in every wound, and the distinction between pathogens and non-pathogens is not clear cut; but, broadly speaking, the organisms now recognised as capable of causing sepsis by invasion of tissues are the coagulase-positive *Staph. aureus, Streptococcus pyogenes, Pseudomonas pyocyanea,* and *Proteus vulgaris.* The last two are seldom found ab initio; they are later additions.

On bacteriological grounds it can be stated that the *immediate closure of the recent open wound is safe* provided the wound is free from all dead or dying tissue which could act as a nidus for the growth of pathogenic organisms, including anaerobes.

THE EVIDENCE FROM EXPERIMENTAL PATHOLOGY

The work of Sir Almroth Wright (1919) goes further than this, for he proves that even where there is moderate contamination and infection the wound can combat this best when it is closed. In 1919 he said: " if he [the surgeon] provides the requisite conditions—and he does provide them when he excises all devitalised and heavily infected tissues and brings together the walls of the wound—the protective mechanism of the body can, without any antiseptics, deal successfully with every kind of infection."

TABLE I—WOUND BACTERIOLOGY ON ADMISSION

Author	Material	Age of wounds (hours)	Wounds free from pathogens* (%)
Colebrook, Duncan, and Ross (1948)	734 recent burns and scalds	—?	90
Williams and Miles (1945)†	432 fresh lacerations of hands	0·6	78·2
Hare and Willitts (1942)	355 fresh wounds	2	90
De Waal (1943) ..	708 fresh wounds	10	80
Altemeier and Gibbs (1944)	99 fresh wounds	3	*c.*90
Cooper and Williams (1945)	134 fresh wounds	0·6	80
Bentley and Thompson (1945)	100 war wounds	?	49

* Organisms regarded as pathogenic include the coagulase-positive *Staph. aureus, Strep. pyogenes, Ps. pyocyanea,* and *Proteus vulgaris.*

† In cases contaminated only with *Staph. aureus* a few colonies were grown.

TABLE II—WOUND HEALING BY FIRST INTENTION

Author	Material	% healing by first intention	
		Immediate closure	Delayed primary closure
Ehalt and Bohler (1926)	127 open fractures	86·6	..
Davis (1948)	150 open fractures	87	..
Birmingham Accident Hospital	95 open fractures of tibia	95	..
Stammers (1948) ..	180 war wounds	90	..
Hendry (1945) ..	166 open fractures of war	..	90
Cleveland and Grove (1945)	5042 open fractures of war	..	93
Edwards (C.M.F. figures) (1945)	343 war wounds and fractures	..	94
Lawrence and Sturgis (1946)	1110 war wounds and fractures	..	84·4
Brown (1945)	721 war wounds	..	91·4
Bentley (1944) ..	200 war wounds	..	95
Murray (1945) ..	729 war wounds	..	85
Wilson (1945)	224 war wounds	..	96
Churchill (1944) ..	c.25,000 war wounds (clean on gross appearance)	..	c.95
Kirtley and Trabue (1944)	217 war wounds	..	92·7
Farris and Jones (1947)	725 war wounds	..	96

In all these cases healing was said to be satisfactory, though in a small proportion the scar was " moist " for a few days. The majority of war wounds were dusted with sulphathiazole and/or penicillin powder.

From his research at Boulogne during the first world war he advocated closure of wounds (after excision) in order to eliminate any residual bacterial infection. His principles are so true today that they are worth repeating in his words:

> " (1) The procedure here enjoined is that which nature herself employs. She extinguishes the wound infection only by closing the wound.
>
> " (2) There is in the modus operandi of closure employed by nature one outstanding defect. The epithelium grows in only very slowly from the edges of the wound. In consequence of this dilatory ingrowth the bacterial infection will in extensive wounds persist for indefinitely long periods, with the result that contracting scar tissue takes the place of the normal epithelial covering.
>
> " (3) By artificial closure, whether by suture, by drawing together of the edges by strapping, or by skin grafting, the wound is promptly sealed, with the result that the bacterial infection is rapidly extinguished and the formation of scar tissue is avoided " (Wright 1933).

THE EVIDENCE FROM PRACTICE

Is the evidence from bacteriological study and experimental pathology supported by practice? Ehalt and Böhler (1926) achieved 87% primary healing in 127 open fractures closed at once. Davis (1948) in Pennsylvania has reported 87% first-intention healing of wounds in 150 compound fractures.

Between 1941 and 1948 at the Birmingham Accident Hospital, 95 open fractures of the tibia and fibula were treated. Of these, 85 were closed at once and only 4 became infected (5%). The 10 treated by the Trueta technique all became infected.

Cleveland and Grove (1945) reported 93% successes with delayed primary suture in over 5000 open fractures from the battlefields of Europe—cases believed to be the most seriously contaminated of all. Kirtley and Trabue (1944) record the same rate of successful healing; Farris and Jones (1947) produced 96% successful healing in 725 wound closures, whether local chemotherapy was used or not, and Churchill (1944) reported about 95% successful healing in 25,000 war wounds closed by delayed primary suture, selected on gross appearance only. If they were still clean at five days then they could, under other circumstances, have been closed on the first day (table II).

In war, under field conditions and the pressure of work, delayed primary closure is the right treatment still : *in civilian surgery primary closure is safe in most* accidents. Greater judgment is needed with injuries from direct violence, for contamination is found mainly in this group. With multiple injuries, where shock may dominate the clinical picture, the general condition of the patient may preclude a long operation. In these cases, and in some with gross soft-tissue loss or damage, immediate excision and delayed primary closure may be the right treatment. Individual surgeons will have to judge whether the facilities in their hospital make delayed primary closure necessary, but casualty departments will have to be improved until immediate excision and suture is possible in every case where the wound permits it.

THE EVIDENCE OF THE DANGER OF ADDED INFECTION

Is it, however, as safe to leave a wound open ? Is hospital infection—airborne and added infection—a myth or a most serious danger ? Added infection can occur only where there is a wound to add it to.

The work of Miles et al. (1940), McKissock et al. (1941), Bourdillon and Colebrook (1946), Colebrook et al. (1947), and a multitude of others on hospital infection has shown that a great reservoir of pathogenic organisms exists in every hospital—on blankets, dirty dressings, wounds, and the skin and noses of patients and staff alike—and these workers have described in detail the elaborate techniques necessary to prevent these organisms from reaching the open wound, where they can cause infection.

Atmospheric or airborne contamination from this reservoir can be blamed for much of the added infection which occurs. Such contamination can very easily be studied by the Bourdillon et al. (1941) slit sampler in which the air which is suspect is passed through a slit at a known volume per minute. Beneath this slit a blood-agar plate or other suitable medium is slowly revolving. This plate is then cultured. Slit sampling the air of wards, dressing-stations, and operating-theatres has demonstrated high atmospheric counts of pathogenic organisms after disturbance of blankets, pyjamas, and dirty dressings, and after sweeping, bed-making, and walking (fig. 2).

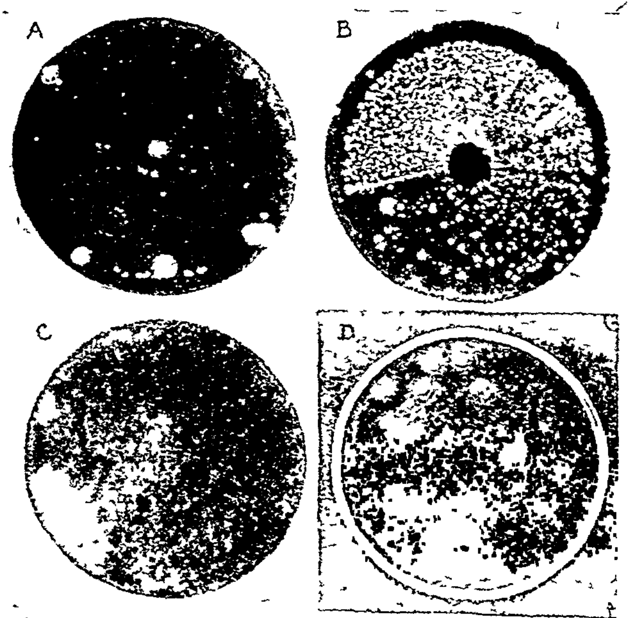

Fig 2—" Bacteriograms " showing air contamination by organisms.
(A) Clean air in the burns dressing-station after slight traffic in the room (1·18 organisms per c. ft.).
(B) During removal of bandages of a clean shoulder burn (67·5 organisms per c. ft).
(C) Air free from organisms in air-conditioned dressing-room 15 minutes after removal of patient (0·12 organisms per c. ft.).
(D) Air contamination with *Proteus vulgaris* from infected case.

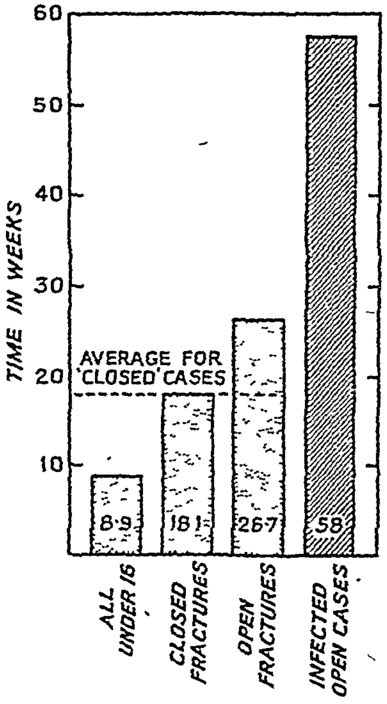

Fig. 3—Average times for union in 217 tibial fractures treated at the Birmingham Accident Hospital, 1941-45.

The shower of pathogens released into the air hovers and slowly settles, readily infecting an exposed open wound or landing on a plaster or bandage. Owens (1943) and Colebrook and Hood (1948) proved experimentally that a dressing or plaster soaked with tissue fluids acts as a semi-solid culture medium through which pathogens can grow in a few hours. De Waal (1943), who showed that only 19% of all wounds on admission contain pyogenic staphylococci, found that 86% of all wounds left open, and 67% of all burns, became infected during treatment, and he also found that wounds treated by first-aid " cleaning " were much more often contaminated than wounds merely covered with a sterile dressing.

Orr-Ewing et al. (1941) made a careful bacteriological survey of wounds treated by the Trueta technique in plaster and found new flora between the third and twelfth day in every case. They *concluded that these were* initial contaminants with delayed growth, but they did not prove that the organisms did not grow through the dressing ; and it can be assumed that these were in fact all examples of added infection. Wilson (1945) obtained healing without infection in 85% of cases sutured under ten days, but in only 38% of those sutured after ten days, and he found that the higher proportion of failures was due to infection. De Waal (1943) noted that 34 out of 38 wounds treated in closed plaster became infected during treatment.

The 14 cases (10 ab initio and 4 which broke down) of open fractures of the tibia and fibula treated at the Birmingham Accident Hospital by the Trueta technique all became infected ; they took on an average fifty-eight weeks to unite, and 1 died after a year, from infection. In the remainder of the open fractures treated the average time for union was twenty-six weeks (fig. 3). Arnaud et al. (1939), analysing 600 cases treated by the Trueta technique in the Spanish war, record that about half the patients—and all the open *femoral fractures*—suffered from infection, deformity, osteomyelitis, and delayed union.

Eighty years ago added infection was expected to follow every open wound and operation : hospital gangrene made the decision to operate into a death-warrant. Today we criticise our work carefully every time a clean wound fails to heal.

We do not expect infection in a clean wound we have closed. This statement stands in strong relief against the absolute certainty of infection in a wound we have left open, unless we are prepared to enact the careful ritual in bacteriologically clean, air-conditioned dressing-rooms and operating-theatres which the prevention of airborne added infection demands (Bourdillon and Colebrook 1946).

EARLY CLOSURE OF WOUNDS

The evidence suggests:

1. That most wounds are clean on admission, and that after prompt and careful excision of devitalised tissue immediate closure is safe whether the wound is complicated by fracture or not.
2. That such early closure is desirable because healing is more rapid and fibrosis thereby cut to a minimum. Function is thus more completely restored and painful scars are eliminated.
3. That, because of the great danger of added infection unless elaborate precautions are taken, early closure is imperative if life and limb are to be saved.

This plea for early closure of the open wound is no academic matter: every day many hundreds of lacerations—some small, some large—are sustained by men and women at work in industry and in the home, many of them being injuries of the hand; open fractures are common, and the largest open wound of all, the burn, is a frequent occurrence. The cost of these injuries in suffering, in lost time, and in hard cash is enormous.

It is the doctor's duty to his patient and to the community to minimise them so far as he can. It is possible by careful excision and closure of wounds at least to halve the time needed for the treatment of simple lacerations, and we cannot ignore the difference between twenty-six weeks for union in the open fractures of the tibia which were closed, and fifty-eight weeks (with 1 death in 14 cases) where the wound was allowed to remain open.

PRINCIPLES OF TREATMENT OF THE OPEN WOUND

I would urge that the five principles of treatment of the open wound enunciated by Trueta should be modified. In the light of experience, and where the conditions are suitable in civilian surgery, traumatic open wounds, whether complicated by fracture or not, should be treated on the following principles:

1. Prompt surgical treatment.
2. Cleansing of the skin around the wound.
3. Excision of devitalised and non-viable tissue.
4. Immediate closure by suture or skin graft.
5. Abolition of dead spaces by firm pressure-dressing, and plaster if necessary.

I believe that if these principles are universally adopted infection will almost disappear, the lifelong misery of chronic osteomyelitis after an open fracture will be abolished, wounds will heal more quickly, fibrosis and deformity will be minimal, and function will be maximal.

II. The Technique of Early Closure

THE FIVE REQUIREMENTS

1. *Prompt Surgical Treatment.*—No-one will dispute that surgical treatment should be given at the earliest possible moment after trauma. Bohler stated that in cases first seen after six hours primary excision and closure was not advisable. With the evidence of the bacteriological picture at various stages after the infliction of the wound (Pulaski et al. 1941, Cooper and Williams 1945) and the experience of delayed primary closure, it is apparent that this interval can be safely prolonged to twenty-four hours or even more. A screen of systemic penicillin renders this safer and the need to prevent added infection makes it permissible to run the risk of a "moist" wound which takes a few days longer to heal. After twenty-four hours, when added infection by pyogenic bacteria has almost certainly occurred, excision and delayed primary closure is the better treatment.

2. *Cleansing the Skin around the Wound* is a most important part of the procedure. It has been shown that 1% cetrimide (C.T.A.B.) is a very efficient means of preparing the skin in the theatre for immediate operation. It is an excellent detergent for oil, grease, and road dirt, and thorough cleansing with cetrimide for four minutes will leave the skin clean and sterile (Williams et al. 1943, 1944). Repeated application tends to cause scaling and dryness with delayed healing; so it is not suitable for a forty-eight-hour preparation. Sensitivity has been reported but is very rare (Cruickshank and Squire 1949).

3. *Excision of Devitalised Tissue.*—The technique of wound excision is so well known that detailed recapitulation is unnecessary. What is essential is to provide a viable bed of healthy living tissues from which all dead and devitalised material which could act as a nidus for infection has been removed. Surgeons agree that the commonest cause of failure in delayed primary closure is residual dead tissue in the wound (Arnaud et al. 1939, Churchill 1944, and others). Local sulphonamides appear to contribute nothing to success in primary closure, except a false sense of security; if they are relied upon to the detriment of excision, they lead to worse results (Churchill 1944, Meleney 1945). Local penicillin is, however, of value in war wounds (Mason Brown 1944), and we may reasonably assume that this holds true for civilian practice.

From the practical point of view, however, the problem is not so simple. At the time of operation it is often extremely difficult to decide what tissues are in fact viable. This is particularly true of muscle, where necrosis may result from local damage to, or from remote interference with, the blood-supply. Late swelling may place in jeopardy the circulation in a muscle, or part of a muscle, which is living at the time of the excision. Our knowledge of the exact anatomy of the blood-supply to each muscle is scant, and the effect on the muscles of interference with the circulation in individual vessels—by trauma, spasm, or pressure—is largely unknown. The need for further study is great; for dead muscle or parts of a muscle must be accurately localised and excised if success in the treatment of a wound by any means is to be ensured, and if the danger of gas-gangrene is to be eliminated. Until we have more knowledge, we must depend upon loss of contractility and failure to bleed; though each of these guides is unreliable. In recent cases alterations in colour are not always observed, even when the whole muscle is dead.

4. *Immediate Closure by Suture or Skin Graft.*—Closure of the wound is accomplished by interrupted silk sutures, placed close together and carefully inserted to provide edge-to-edge apposition of the skin. No tension must be present, especially over bone, and if swelling or skin loss prevents closure without tension then closure must be achieved by other means.

5. *Abolition of Dead Space and Prevention of Post-traumatic Œdema by Pressure-dressing.*—The abolition of dead space, and the control of œdema, by means of carefully applied pressure-dressings of crêpe bandage over quantities of wool is a most important part of the procedure (Blair 1924). Elevation of the part concerned is essential during the first few days. The value of even pressure after trauma is another of the great lessons we have re-learned during the late war.

TREATMENT OF WOUNDS WITH SKIN LOSS

When damage or actual loss of skin complicates the open wound, even the surgeons who normally close their wounds often abandon their principles, speak glibly of contamination or drainage to cover their discomfiture, and then leave the wound open to heal as best as it may. Healing under these conditions, even if infection can

Fig. 4—Transposition flaps to close small skin defect in open fracture of tibia, with split-skin grafting of secondary defect.

be avoided, is always by fibrosis and is long delayed. Open wounds, with or without a fracture, where skin has been lost must still be closed at once, and it is worth considering the various ways in which this can be done.

Split-skin Graft

The simplest, safest, and most certain way of covering a skin defect is always a split-skin graft, and such a graft will take on any viable bed which does not have in its base :

(*a*) cortical bone deprived of periosteum (a split-skin graft will take on living cancellous bone) ;
(*b*) tendon deprived of paratenon ; or
(*c*) cartilage (though a thin split-skin graft will even bridge about 4 mm. of this—e.g., an intertarsal joint).

These grafts should be cut thin, unless a thicker graft is particularly required ; they should be applied to a living bed, pressed home with firm pressure by wool pledgets containing paraffin or saline solution, and covered with wool and a crêpe bandage. Where the surrounding tissues are normal the graft should be sutured into place. It is most important to see that the graft is cut much larger than the wound to be covered ; for by the time it has been pressed into every crevice the excess will be taken up, and cover without tension will still be achieved.

The main causes of failure in split-skin grafting are :

1. A non-viable bed after inadequate excision.
2. Hæmorrhage beneath the graft. This is often encouraged by imperfect apposition when too small a graft is stretched over the wound.
3. Failure of immobilisation until the graft has taken.

The split-skin graft may not be suitable as a permanent cover, for one reason or another : the site may be subject to heavy wear and tear, the graft may be unsightly, or further operations such as arthrodesis or tendon-grafting may be necessary beneath it for functional reasons. At two or three weeks from the injury, other things being equal, the split-skin graft may be replaced by a flap graft or pedicle with certainty of minimal fibrosis and an absence of infection.

Corachan (1933), Reverdin, and Wolfe grafts are not suitable for the recent wound.

Split-skin grafts are so useful for a multitude of purposes that the acquisition of skill in cutting them should be an essential part of the training of every medical student. The technique presents no difficulty that practice and a really sharp knife cannot overcome.

Transposition Flaps

In the limbs this method is of limited value for acute trauma and is suitable for only small defects. Damage to the circulation and soft tissues of the limb always extends far more widely than the area of the wound, and this disturbance of normal physiology and blood-supply jeopardises the viability of the skin during the acute stage of the injury. It is dangerous to take any liberties with skin at this time, for large areas may slough as a result. Relieving incisions, placed well away from the wound to avoid necrosis of the bridge, are a form of transposition flap which will sometimes allow closure of the skin over bone ; but where it means that the surgeon increases the undermining caused by the trauma, this method should probably not be used. The secondary defect over muscle can be grafted with split skin. Undermining the skin to the extent suggested by Otto (1947) is not safe in acute trauma. Alternatively the defect can be extended by curved incisions with as large a radius as possible and the flaps so formed rotated slightly on their base (fig. 4).

Flap Grafts

There is undoubtedly a place for the immediate flap graft from leg to leg, or (rarely) from abdomen or arm to arm ; so the surgeon who treats wounds should be familiar not only with the technique but also with the complications and dangers in acute cases. There is no other means of getting early closure, for example, in the severe open fracture of the leg with extensive skin loss or destruction, where after excision of non-viable tissues and skin a grossly unstable fracture lies widely exposed. Such a fracture can first be stabilised with a plate, and a cross-leg or cross-arm flap can be applied with as wide a base as possible. In acute trauma a base-length ratio of at least 2 to 1 is essential if the flap is to take successfully, and skin should be sacrificed to allow these proportions. At the Birmingham Accident Hospital 4 such cases have been done in the last eight years, but it is possible that with increasing technical knowledge more severely injured limbs (particularly upper limbs) will be saved by this means (fig. 5). It

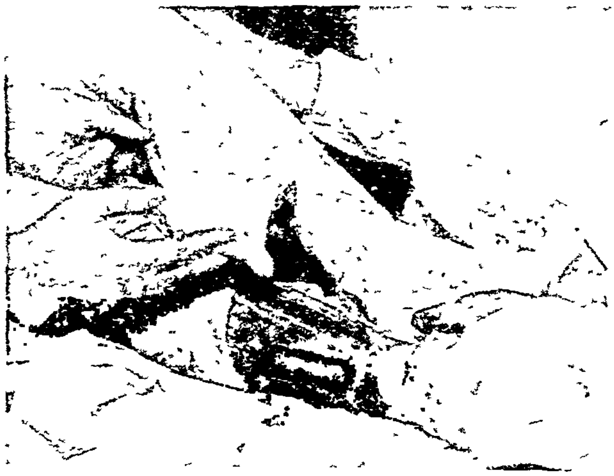

Fig. 5a.

Fig. 5b.

Fig. 5—(*a*) Primary plating and cross-leg flap to unstable fracture of tibia and fibula with considerable skin loss. (*b*) First-intention healing of wound. Union of fracture in ten weeks. Symptom-free since discharge two years ago.

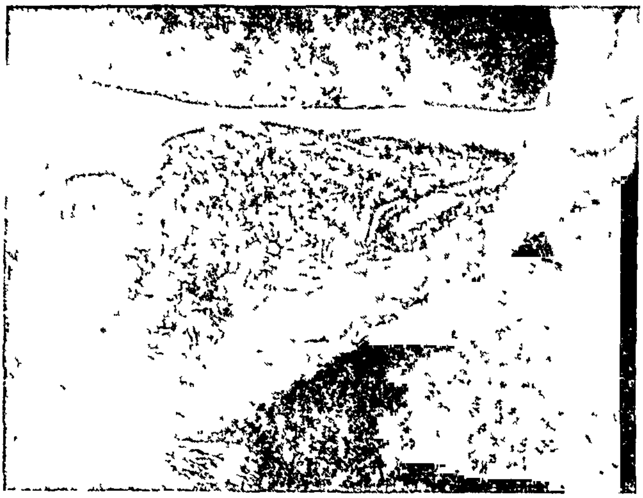

Fig. 6a.

must be emphasised, however, that performance of a cross-leg or cross-arm flap two or three weeks later, the wound having been closed initially by a Thiersch graft, is much safer, more desirable, and easier (fig. 6). The technique for these flaps has been well described by Braithwaite and Moore (1949).

In suitable cases, however, small flaps to the ends or sides of fingers following traumatic amputations are well worth while. The flap is applied with the same attention to detail as the larger ones, including thick split-skin grafting of the donor area and the careful suture of the return flap so that no bare area is left. Such flaps can be fashioned from the adjacent skin of palm or finger (which provides the best-quality cover) or from the skin over the extensor mass of the opposite forearm.

PROBLEM OF "DEGLOVING" OR POTENTIAL SKIN LOSS

With extensive degloving or stripping of the skin from the subcutaneous tissue, where the separated skin retains a limited attachment, it is hard to know how much of the flap will survive. The problem is to decide whether such skin should be scrapped on sight, or replaced on the chance that some or all may live. It is well to remember that even dead or dying skin will act for a time as a barrier to added infection, though it will *not* prevent the formation of granulation tissue between the living and dead tissues. An arm caught in rollers may, by a violent twisting movement applied to the skin, be effectively degloved without an external wound of any sort. In such a case, of course, swelling of damaged muscle and hæmatoma formation may destroy by pressure the last chance of skin survival unless the pressure is relieved. There are no hard and fast rules about the survival of degloved skin: a bleeding edge may or may not denote survival (for thrombosis in the base may occur later), and a flap which does not bleed may live in its entirety or in part. In one case of extensive degloving of the leg in a child we observed survival of degloved subcutaneous tissue and fat with death of the overlying skin. Greater experience may lend inspiration to a guess; but, in general, degloved skin should be sutured back into place in preference to excision unless conditions for immediate replacement are very suitable.

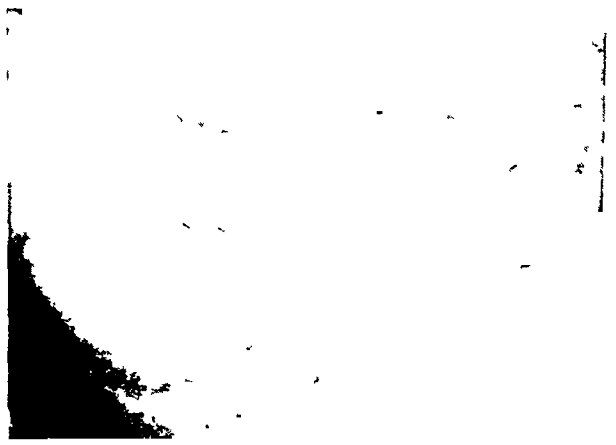

Fig. 6c.

Fig. 6—(a) Dirty wound of foot with skin loss, exposing joints, treated by primary split-skin graft. (b) Replacement by pedicle graft completed at sixteen weeks (c).

THE MAJOR HAND INJURY

Injury by power-driven saws, the guillotine, or the power-press often produces a severely damaged hand in which form has been irretrievably destroyed. The provision of skin cover is the surgeon's first duty, but in achieving it he must bear future function in mind. By ingenious exploitation of tags of surviving skin, by filleting damaged fingers which can be spared, he can often provide a hand in which the vice action of gripping and the pincer action of apposition are represented. Ruthless amputation is wrong, but the sacrifice of damaged digits to provide skin cover for essential function is justified (Evans 1949).

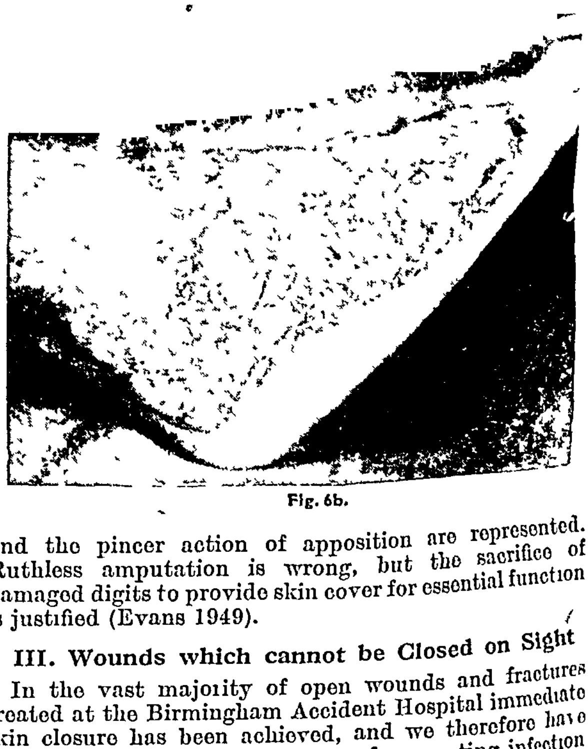

Fig. 6b.

III. Wounds which cannot be Closed on Sight

In the vast majority of open wounds and fractures treated at the Birmingham Accident Hospital immediate skin closure has been achieved, and we therefore have little experience of the problems of preventing infection in open fractures treated without closure. Nevertheless the Burns Unit has shown conclusively the value of preventing added infection in burns (Colebrook et al 1947, 1948) and details of the technique of prevention have been published. For all practical purposes the burns with partial skin loss, and those cases of whole skin loss in which primary excision and closure by graft is not done, can be regarded as open wounds. In them, as in open fractures, the protection afforded by the intact epithelium against infection has been lost. It is logical, therefore, to argue that a technique applicable to burns applies equally to the open wound.

It has been proved that infection of a burn during healing can be largely prevented. Colebrook and Hood (1948) point out that a fourfold attack is necessary.

1. No pathogens must be allowed to reach the wound at the time of dressing.

2. No pathogens must be allowed to reach the wound between one dressing and the next.
3. The reservoir of pathogens in the wards must be kept as low as possible (by eliminating them from the wounds which have them).
4. Raw surfaces must be reduced by early grafting.

These four principles are as true for the open wound as they are for the burn; but, their application in practice, as achieved in the Burns Unit at the Birmingham Accident Hospital, involves moderate expense, devoted and unremitting care, and unlimited patience.

Prevention of Infection During Dressings.—A very careful no-touch technique is practised, but recognition of the danger of airborne infection, and the provision of an air-conditioning system to prevent it, has proved so strikingly successful that its use elsewhere is now fully justified both for dressing-stations and for operating-theatres. The principle of flushing out all organisms mechanically by an abundant stream of filtered air is discussed fully by Bourdillon and Colebrook (1946). The evidence is now such that there can be little excuse for failing to guard against added infection by this means wherever open wounds are exposed.

Prevention of Infection between Dressings.—Perfect cover of a wound is always difficult to maintain; in fact Colebrook et al. (1947) stated that "the incidence of added infection in burns which were found to be imperfectly covered when they arrived for re-dressing was ten times as high (8·6%) as that of the burns which had perfect cover throughout the period between dressings (0·8%)." In view of the experimental evidence of Owens (1943) and Colebrook and Hood (1948) that organisms can grow rapidly through a soaked dressing or plaster, it can no longer be accepted that closed dressings or plasters provide safe protection against added infection, for the majority become stained with blood and tissue exudate. Recently, however, a semi-permeable membrane has been devised of such a molecular structure that organisms cannot, but water vapour can, pass freely through it (Bull et al. 1948). This 'Nylon' derivative, at present undergoing clinical trials, can be sealed to the skin round the wound under the dressing and should act as an effective barrier against organisms. Its permeability to water vapour prevents sogginess and maceration of the skin.

Elimination of the reservoir and reduction of raw surfaces have been discussed earlier.

IV. Conclusions

The evidence in favour of early excision and primary closure of traumatic open wounds and fractures is overwhelming. The experiences of all who have practised it, and the scientific data accumulated to prove its safety and desirability, cannot be ignored. There is no doubt that delayed primary closure is the correct treatment both in war and in certain conditions of civilian life; but the provision of a whole healthy skin must be the surgeon's most urgent task. Until the wound has healed, restoration of function cannot begin, and if healing is delayed, or accompanied by infection or fibrosis, then crippling deformities and stiff joints may be the immediate sequelæ.

The argument for careful excision and early closure applies to every open wound, be it a small laceration or a massive open fracture with extensive skin loss: until the skin is healed no reconstructive surgery or restoration of function can be started. Every minute a wound is left open increases the risk of added infection, with its danger to future function, to the life of the limb, and even the life of the patient.

In major and minor hand injuries fibrosis from healing by second intention will inevitably interfere directly with function, and there is no more potent cause of frozen useless hands than chronic infection and immobilisation. Primary healing is the sine-qua-non of full function after hand injuries.

The burn with partial thickness cannot be closed at once; yet infection can be avoided, provided that faithful and loyal attention is given to every detail of the elaborate technique which alone can prevent it. In peace-time it is rare to encounter an open wound which cannot be closed at once; but when this happens it should be treated by the same technique.

Skin is the only safe barrier to added infection—it is the barrier nature has designed for this purpose—and deep tissues are perfectly well able to deal with a few colonies of initial contaminants provided only that they are viable and healthy.

The present-day view can be summarised adequately in the words of Furlong and Clark (1948): "Infection of a wound can be excluded only by surgical closure and this must be done at the optimum time although its accomplishment may tax the ingenuity of the surgeon to the utmost."

I am indebted to my surgical colleagues at the Birmingham Accident Hospital for help and criticism in the preparation of this paper. I would also express my thanks to Mr. William Gissane, Dr. Leonard Colebrook, F.R.S., and Mr. Ruscoe Clarke for permission to use photographs from their records, and to Mr. N. R. Gill of the photographic department for preparing the illustrations.

IDIOPATHIC STEATORRHŒA (NON-TROPICAL SPRUE) WITH MEGALOBLASTIC ANÆMIA

M. C. G. Israëls
M.D., M.Sc. Manc., F.R.C.P.
LECTURER IN HÆMATOLOGY, UNIVERSITY OF MANCHESTER

J. Sharp
M.B., B.Sc. Manc., M.R.C.P.
SENIOR REGISTRAR, MANCHESTER ROYAL INFIRMARY

Liver treatment for the tropical and non-tropical varieties of steatorrhœa with macrocytic anæmia has been recommended for many years, though it has been known that the response is unpredictable. When bone-marrow examinations were made in these patients, only some were found to have a megaloblastic picture like that seen in pernicious anæmia; a reasonable inference, therefore, was that only those with such a marrow change could be expected to respond to liver extracts prepared for the treatment of pernicious anæmia. But, once again, expectation was not borne out in practice, and patients whose anæmia was more or less resistant to liver treatment were still encountered. The advent of folic acid (pteroyl-γ-glutamic acid) provided a new line of approach, because some of the earliest reports on the effect of folic acid in the West Indian form of tropical sprue showed that there was a remission of the megaloblastic anæmia, and the accompanying symptoms of sore tongue, anorexia, and the passage of bulky fatty stools were dramatically relieved (Darby et al. 1946, Garcia Lopez et al. 1946). There was thus a clear indication for giving folic acid to patients with non-tropical sprue, and the results have been encouraging, though the number of adequately studied cases is relatively small.

Moore et al. (1945) gave 20 mg. of folic acid intravenously daily for ten days to a patient with non-tropical sprue with macrocytic anæmia and megaloblastic marrow; they reported a brisk reticulocytosis and slight improvement in red cells and hæmoglobin. Davidson and Girdwood (1946) and Davidson et al. (1947) described 3 cases of non-tropical sprue treated with folic acid by mouth with satisfactory clinical effects, such as prompt cessation of diarrhœa, improved appetite, and a sense of well-being; fat-balance tests with 50 g. of fat daily for three days showed defective fat-absorption, which, however, was unaffected by treatment. The marrow was frankly megaloblastic in 1 case, and occasional megaloblasts were reported in the other 2 cases. Only 1 patient showed a good hæmatological response to folic acid; the red-cell count rose from 1,370,000 to 3,590,000 per c.mm. in twenty-nine days; but no further rise could be obtained, and subsequent injections of 'Anahæmin' were also without effect; however, the red-cell count increased by 1,000,000 per c.mm., and the mean cell volume returned to normal, after fourteen days' treatment with an oral proteolysed liver preparation. This patient had previously had a megaloblastic marrow and had proved refractory to potent liver extracts. From these and other observations Davidson and his co-workers suggested that some other factor, presumably present in liver, is necessary for the complete repair of the anæmia. Davidson (1948) has also given brief details of 25 patients classified as "idiopathic refractory megaloblastic anæmia," 5 of whom were refractory to anahæmin but responded promptly to folic acid.

Wilkinson (1948) described 3 patients with non-tropical sprue who had some megaloblasts present in the marrow before treatment; 1 responded very well to treatment and 1 responded slowly but quite well, but in the third the response was poor.

Ferguson and Calder (1948) reported 7 cases of non-tropical sprue treated with folic acid by mouth, but they were mainly concerned with the effect of the treatment on fat-absorption and the radiological appearances in the small intestine; none of their patients had severe anæmia, and no hæmatological improvement was noted during treatment. In 2 of their patients the marrow was normoblastic; 2 others initially had a megaloblastic marrow but, by the time folic acid was given, they had already been treated with an oral liver preparation and had responded.

No report has so far appeared about the action of folic-acid conjugates in non-tropical sprue; but Spies and Suarez (1948) reported that a case of tropical sprue showed a typical response when pteroyltriglutamic acid was given, and another case responded similarly to pteroyldiglutamic acid.

Vitamin B_{12} also has been given to patients with non-tropical sprue. Spies et al. (1948, 1949a and b) reported the effect of a single dose of 6 µg. on a patient with this syndrome having a megaloblastic marrow; in spite of a reticulocyte rise of 22·3%, the response was poor and not sustained. Spies et al. (1949b) also gave vitamin B_{12} by mouth to 2 patients with non-tropical sprue; one dose of 50 µg. had no effect, but 450 µg. daily for six days produced a slight response, with a rise in red-cell count from 1,730,000 to 2,320,000 per c.mm. fourteen days after treatment began; reticulocytes increased to 9·1% on the fourth day.

The patients described in the above-mentioned reports were all known to have steatorrhœa; some had had it for years. We are reporting here 5 patients who had a megaloblastic anæmia refractory to liver treatment and were not known to have steatorrhœa at the time of its onset—in fact, in 2 of the patients there were few symptoms to suggest the correct diagnosis to those who had been looking after them. These patients were refractory to liver treatment, and in 3 cases we found that they were refractory to vitamin B_{12}. They did respond, however, both clinically and hæmatologically to folic acid. We are reporting these cases to draw attention to the difficulty of clinical diagnosis, the possibility of effective treatment, and the influence of such findings on our views on the ætiology of megaloblastic anæmias.

CASE-RECORDS

Case 1.—A female clerical worker, aged 17. In January, 1948, when 16 years old, this patient first noted slowly increasing fatigue, breathlessness on exertion, decrease in appetite, and pallor; she lost a little weight. Early in August, 1948, her doctor prescribed iron tablets, but they had no effect. In late August, within a few hours, she developed rapidly progressing weakness with dysæsthesiæ first in the right leg and then in the right arm; she went to bed and three days later was admitted to another hospital. Examination revealed a pale girl, very underdeveloped for her age, with no body hair, and with clubbed fingers and toes. The spleen and liver were palpable 1 cm. and 5 cm. respectively below the costal margin. Her knee-jerks and ankle-jerks were absent, there was an extensor plantar response on the right side, and there was well-marked relative weakness of the right lower limb without increase in tone. She was very anæmic, and a blood-transfusion was given at once. Blood-counts are shown in the accompanying table. After the transfusion the neurological symptoms and signs disappeared; a week later the liver and spleen were no longer palpable. At this time a test-meal showed free HCl in the gastric juice; liver function-tests were normal, and tests for occult blood in the fæces were negative. During the first seventeen days in hospital the patient received daily injections of 2 ml. of anahæmin and, since she had a low pyrexia up to 100°F, she was given penicillin by injection as well. There was no response to the anahæmin, and further blood-transfusions were necessary. The patient's sternal marrow was now reported as normoblastic; 1 megaloblast was seen among 15 erythroblasts counted in 250 cells.

After some time the patient again relapsed and was transferred to Manchester Royal Infirmary on Nov. 13, 1948.

Questioned at this time, she said that her growth and development were normal until about the age of 9 years, when they almost ceased; she had never menstruated; her mental development and interests were normal for a girl of 16. Soreness of the tongue had developed in August but soon subsided. She stated that bowel movements and stools seemed normal. No relevant previous medical history was given.

On examination, apart from the anæmia and clubbing of the digits previously noted, the patient presented the typical picture of pituitary infantilism with prepubertal genitalia and no secondary sex characters. Her height was 60 in. with body measurements in proportion, and body-weight 84 lb. Mild glossitis was noted; the abdomen was somewhat protuberant, and the liver edge could be felt. Investigation now showed a severe normochromic anæmia, with 1,570,000 red cells per c.mm., Hb 4·6 g. per 100 ml., mean corpuscular volume 96 c.μ, mean corpuscular diameter 7·6 μ; serum-proteins 5·6 g. with albumin 3·4 g. per 100 ml.; serum-bilirubin 1·0 mg. per 100 ml.; thymol-turbidity and alkaline-phosphatase normal; and Wassermann reaction negative. An oral glucose-tolerance test with 50 g. of glucose showed a flat curve with maximum rise of 18 mg. above the fasting level of 73 mg. per 100 ml.; an insulin-tolerance test showed normal sensitivity. The 24-hour excretion of 17-ketosteroids was 1·8 mg., and no gonadotrophins were detectable. Aspiration biopsy of vaginal contents was attempted, but no material was obtained. Barium-meal radiographs showed normal stomach, duodenum, and intestinal pattern; radiograms of long bones and skull were normal. Sternal marrow, examined the day after admission, showed typical megaloblastic hyperplasia like that of pernicious anæmia in relapse. The presence of free HCl in the gastric juice was confirmed.

These findings, together with the previously unexplained clubbing of the digits, suggested that steatorrhœa might be present; and the stool was found to be orange-yellow, soft, bulky, and unformed, with an average fat-content of 67·8%, dried weight. It transpired that this was regarded by the patient as a "normal" stool, and her parents, when directly question, revealed that she had had an illness at the age of 5 years, when she had had frequent diarrhœa with light-coloured stools, and that this diarrhœa had persisted, in spite of treatment, until the age of 13. We have since noted this feature in other cases of steatorrhœa; the patients do not know what a normal stool looks like.

A twelve-day fat-balance test with 70 g. of fat daily showed 79·8% absorption, but this figure may be low because the patient's appetite was capricious and she therefore left some of her food.

In the meantime the patient had four blood-transfusions. The first, of packed red cells, when her hæmoglobin had fallen to 3·8 g. per 100 ml., was given because of recurrence of the dysæsthesia and motor weakness in the right arm and leg associated with motor aphasia; her symptoms were promptly relieved, but some days after this episode she noted blurring of vision, and widespread flame-shaped hæmorrhages were seen in both retinæ. All further transfusions were therefore of fresh citrated blood.

Folic-acid treatment was started on Dec. 7, 1948, 20 mg. being given daily by mouth, and 100 mg. intravenously on Dec. 8. Clinical and hæmatological response was prompt; reticulocytes increased to 17·4% on the seventh day, when the sternal marrow showed normoblastic hyperplasia. Almost immediately her appetite and general condition improved, and she began to gain weight. No change was noted in the frequency or character of the stools. A month after the start of treatment a 24-hour urine contained 12 mouse units of gonadotrophin and 10·6 mg. of 17-ketosteroids; a week later a vaginal smear showed no evidence of œstrin effect, but after a further eleven days a smear showed about 50% of the epithelial cells keratinised, indicating œstrin activity.

The hæmatological improvement was steady (see table). After a month's folic-acid treatment, when the blood-count was almost normal, a further twelve-day fat-balance test showed only 61% absorption, and the fæcal fat was still high—69% of dried weight.

Folic acid 20 mg. daily has been continued, with a high-protein low-starch low-fat diet. After two months' treatment slight enlargement of the breasts and external genitalia was noted and some pubic hair appeared. The 24-hour urinary excretion of gonadotrophin was almost 30 mouse units and of 17-ketosteroids was 9·3 mg., and an œstrin effect was observed in the vaginal smear. Development of secondary sexual characters has continued, and menstruation first appeared after five months' treatment with folic acid. The patien has gained 30 lb. in weight.

Case 2.—A female shop-assistant, aged 23. This patient was admitted to another hospital on June 7, 1949, with severe normochromic anæmia. For some weeks she had noted gradually increasing tiredness and some soreness of the tongue. A week before admission she had had an attack of dizziness and severe dyspnœa after climbing a flight of stairs which she normally climbed without effort; she had stayed in bed because of this dyspnœa on exertion.

At the age of 9 years she had jaundice. At 14 she had pneumonia, and thereafter she had occasional mild diarrhœa with watery stools lasting a day or so and always checked with castor oil; no precipitating factor for these attacks was known. In 1945, at the age of 19, she nursed her brother through a severe attack of jaundice and dysentery; after this she felt poorly and stayed in bed for three weeks; there was one attack of diarrhœa with mucus in the stools. During the next year she took a small dose of castor oil daily and had no diarrhœa; but on stopping the oil she again had diarrhœa. Her weight was steady, and there was no dyspepsia. Menstruation had always been irregular, and the menses ceased in April, 1949. At that time a blood-count showed 1,630,000 red cells per c.mm., Hb 4·3 g. per 100 ml., colour-index 0 9. She was treated with anahæmin 2 ml. daily for six days, followed by 'Neo-hepatex' 2 ml. daily for two days, with vitamins A, B, and C, and ferrous sulphate gr. 3 daily. This treatment had no effect, and three blood-transfusions were given. During this period she had an intermittent pyrexia up to 102°F that did not respond to penicillin. She had several small epistaxes, some oozing of blood from the gums, and slight blurring of vision. She was transferred to Manchester Royal Infirmary on June 24, 1949.

On admission she was a small, rather poorly nourished, underdeveloped, and dark-complexioned young woman with gross anæmia. Scattered over the skin of her trunk and extremities were faint chocolate-brown oval macules measuring about 3×2 cm. with superficial scaling; she was not sure how long these had been present. Her tongue showed moderate papillary atrophy, and there was some oozing from the gums. Her liver was palpable 2 cm. below the costal margin, and the spleen was just palpable. The retinæ showed widespread perivascular hæmorrhages and numerous patches of "cotton-wool" exudate.

Hæmatological data are shown in the table. The sternal marrow showed active megaloblastic erythropoiesis. Serum-bilirubin 0·7 mg. per 100 ml. An oral glucose-tolerance test gave a flattened curve with a rise of 37 mg. above the resting level of 81 mg. per 100 ml. an hour after 50 g. of glucose. Free HCl was found in the gastric juice. The serum-iron was 40 γ per 100 ml.; this is a low figure and contrasts with the raised levels found in pernicious anæmia. The 24-hour excretion of 17-ketosteroids was 5·7 mg. and of gonadotrophin 5 mouse units; both these figures are low. Liver-function tests, including bromsulphthalein excretion, were normal. Serum-albumin was 4·0 g. and globulin 2·4 g. per 100 ml. A six-day fat-balance test with 70 g. of fat daily showed 98% absorption. Radiography of the small bowel showed the clumping of the barium commonly present in sprue. Three days later, the patient had mild abdominal colic, relieved by passing a constipated dark stool, and shortly afterwards she passed a loose pale fatty stool—the only macroscopically fatty stool that she had. The fat-balance test was repeated for twelve days with 70 g. of fat daily, and 85% absorption was now found.

While these investigations were going on, the patient was given two blood-transfusions. After the second fat-balance test she was ordered a high-protein low-starch low-fat diet. She was then given vitamin B_{12} 60 μg. parenterally, a dose we have found adequate for initiating a remission in pernicious anæmia. There was no hæmatological response, and the marrow remained megaloblastic. After fourteen days, folic acid 150 mg. was given intravenously. The hæmatological response was striking and rapid, as the table shows. The sternal marrow was completely normoblastic twelve days after the folic acid. Further doses of folic acid were then given by mouth, 20 mg. daily. Clinically the patient improved rapidly; as the anæmia remitted she gained 14 lb. She now passes two formed stools daily, which are paler than before but not bulky or unduly offensive. Menstruation was resumed, but irregularly. The pigmented areas of skin faded rapidly but not quite completely.

On Dec. 1, 1949, three months after her discharge from hospital, the patient complained of aching and swelling of the ankles. The skin of both legs showed severe follicular hyperkeratosis, with hæmorrhages into the papillæ; there were a few small bruises on the forearms and a mild hypertrophic gingivitis. This scorbutic condition responded to 4·5 g. of ascorbic acid given in the next month, and the hæmoglobin rose to over 14 g. per 100 ml. for the first time.

Case 3.—A girl, aged 18. This patient was admitted to the Royal Infirmary under the care of Dr. A. H. Holmes on Nov. 8, 1949, for infantilism and increasing anæmia. She had always been a pale child, and a protuberant abdomen was noted early in life. At the age of 9 years she was sent into a children's hospital, where tuberculous mesenteric glands were diagnosed; the stools at this time were said to be somewhat loose, bulky, and pale. At the age of 13 she was admitted to another hospital because of anæmia; she had a microcytic anæmia with Hb 6·8 g. per 100 ml., and cœliac disease was suspected, but the fat-content of her stools was normal. The anæmia responded partially to iron treatment, and she was transferred to a tuberculosis sanatorium where she remained until the age of $16^{1}/_{2}$. While in the sanatorium, her anæmia fluctuated and her hæmoglobin fell as low as 5·9 g. per 100 ml. at one stage, but on discharge her red-cell count was 4,380,000 per c.mm. and Hb 12·5 g. per 100 ml. However, from that time on her condition steadily deteriorated and her pallor increased. She had never menstruated, and no secondary sex characters had developed. For two years she had complained, on and off, of a sore tongue and sore angles of the mouth.

On admission the patient was small, thin, and very pale; she did not complain of diarrhœa. There was no sexual development, the breasts were flat, and the body hair was almost absent. Her tongue was moist and looked atrophic; there were fissures at the angles of her mouth; her skin was dry and scaling, particularly round the eyes but there was no rash. The heart, lungs, abdomen, central nervous system, and urine showed no abnormalities. Her temperature was raised. Fractional gastric analysis showed some free HCl. The fat in the fæces was 36% of dried weight, and a five-day fat-balance test showed 89% absorption. Radiography showed no unusual intestinal pattern, and no evidence of pulmonary tuberculosis. The serum-bilirubin was raised to 1·5 mg. per 100 ml. She was severely anæmic, with red cells 1,090,000 per c.mm., Hb 4·1 g. per 100 ml., colour-index 1·27, white cells 2200 per c.mm., a normal differential count, and platelets 120,000 per c.mm. The sternal marrow showed a predominantly megaloblastic erythropoiesis, though normoblasts were present as well; giant metamyelocytes were seen.

Fourteen days after admission her red-cell count was 600,000 per c.mm. and Hb 2·4 g. per 100 ml. She was given 100 µg. of vitamin B_{12} intramuscularly. As the table shows, there was no response, and five days later she was transfused with a pint of concentrated red cells; she was also given 120 mg. of pteroyltriglutamic acid ('Teropterin') intravenously. Next day the Hb was 5·3 g. per 100 ml., six days later the reticulocytes, previously below 5%, reached a peak of 37%, and the patient's clinical condition was immensely improved. Further progress can be seen in the table; the marrow changed to normoblastic, and there was a steady increase in red cells and hæmoglobin. Treatment with teropterin was resumed, 40 mg. being given twice weekly intramuscularly. Progress was slow for a time; so 150 mg. of folic acid was given intravenously. The blood-count then improved and on the seventy-second day after admission her Hb reached 12·2 g. per 100 ml. She was then discharged from hospital and ordered 20 mg. of folic acid daily by mouth as a maintenance dose.

Case 4.—A male cinema manager, aged 61. This man was seen at the outpatient clinic on May 23, 1949. Four years previously he had had troublesome flatulence and abdominal distension for four weeks; there was no diarrhœa and the symptoms subsided with simple treatment. In 1947 he began to have attacks of slight diarrhœa every four or five days lasting two or three days, with 3–4 motions daily of normal colour, formed, but soft. About this time he again had postprandial flatulence. These symptoms responded to alkalis, but returned when he had diarrhœa. For the past year he had noted undue fatigue, and for seven months he had had increasing dyspnœa and palpitation on exertion. In February, 1949, he began to take a kaolin mixture for his bowel symptoms, and to this he attributed a change in his stools, which became pale and buttery, contained some mucus, and were unusually offensive. At this time too he had a sore mouth and tongue, which became fiery red for about ten days; there was also slight œdema of the ankles in the evening. His doctor now diagnosed pernicious anæmia and gave him weekly injections of 'Hepastab' 2 ml. together with desiccated stomach $^{1}/_{3}$ oz. daily. This treatment was not taken regularly; his symptoms improved but did not remit. No paræsthesiæ or other neurological signs appeared. He was therefore sent for further advice. Nothing relevant was elicited from his early medical or family history.

On examination in May, 1949, the patient was pale and thin; his skin was dry, and there was a faint brown pigmentation of hands and feet. His tongue was red, with some papillary atrophy. Moderate clubbing of the fingers was present. No other abnormality was found except slight œdema of the ankles, and a moderate anæmia (for blood-counts see table). Barium-meal radiography showed a normal stomach and duodenum, but an unusually coarse pattern was seen in most of the jejunum, without any clumping of barium or undue delay in passage. Treatment was changed to 'Examen' (Glaxo), a purified liver extract, 2 ml. weekly, but there was no response. The patient was therefore admitted to hospital on Aug. 31, 1949.

On admission his sternal marrow showed a hyperplastic pattern; the erythroblasts were mostly normoblasts, but some typical megaloblasts and "transitional" megaloblasts, and the giant metamyelocytes as seen in pernicious anæmia were present. Fractional gastric analysis showed that free HCl was present. Serum-bilirubin 0·4 mg. per 100 ml. A six-day fat-balance test showed only 57% absorption on 70 g. of fat daily. A high-protein low-fat low-starch diet was now given, and after some days' constipation the patient began to pass one or two semi-solid pale motions daily. On Sept. 13, 14, and 15, he was given 20 µg. of vitamin B_{12} intramuscularly, but there was no response. Fourteen days later, folic acid 20 mg. by mouth daily was started. The hæmatological response was slow but definite (see table). The sternal marrow five days after the reticulocyte peak showed completely normoblastic erythropoiesis. The patient's general condition improved with the blood-count; he still had two stools daily, usually formed.

Case 5.—A housewife, aged 29. This young woman has been under observation at the Royal Infirmary since 1940 with a refractory macrocytic anæmia, flatulent dyspepsia, recurrent sore tongue, repeated attacks of pyelitis, and, later, watery diarrhœa with some mucus in the stools. Details of her early history have been reported elsewhere (Wilkinson 1948); a summary with progress notes is given here because she now clearly fits into the group of cases under discussion.

Late in 1945 she began to have pains in the limbs and trunk, the diarrhœa became more severe, and she lost some weight. In April, 1946, the diagnosis of steatorrhœa was established when the fat in the stools was found to be 74% of dried weight. For her anæmia she received many parenteral and oral liver preparations, desiccated stomach, yeast, and B vitamins, and though there sometimes seemed to be a response—particularly with one crude oral liver preparation—relapse invariably occurred while the treatment was still being taken, and blood-transfusion became necessary on 11 occasions. In 1942, after she had received adequate doses of an active parenteral liver extract the sternal-marrow showed a mixed megaloblastic and normoblastic erythropoiesis. Free HCl was found in the gastric juice at this time.

In November, 1946, when the blood-count showed red cells 1,970,000 per c.mm., Hb 7·4 g. per 100 ml., colour-index 1·28, and white cells 3200 per c.mm., folic acid was given by mouth in doses of 20 mg. daily, and all other vitamin treatment was stopped. There was a good hæmatological response; after two weeks her red-cell count was 2,440,000 per c.mm. and Hb 9·2 g. per 100 ml., and after four weeks the red cells numbered 4,100,000 per c.mm. and the Hb was 14·5 g. per 100 ml. After two months the folic acid was reduced to 10 mg. daily, and a normal blood-count was maintained for nine months; the red-cell count was then 5,370,000 per c.mm. and Hb 16·0 g. per 100 ml. Folic acid was now discontinued; for three months her blood-count remained normal but after five months without treatment the red-cell count had fallen to 2,940,000 per c.mm. and the Hb to 11·4 g. per 100 ml. The bone-marrow at this time again showed a mixed megaloblastic and normoblastic picture. Folic acid was given again, 10 mg. daily by mouth, and two weeks later the blood-count was back to reasonable figures: red cells

4,620,000 per c.mm. and Hb 14·8 g. per 100 ml. The patient has since kept up a normal blood-count and has been satisfactorily carried through a pregnancy without relapse, a full-term child being born in July, 1949. More details of her blood-counts are given in the table.

DISCUSSION

The syndrome described here is characterised by (1) a progressive and often severe anæmia; (2) infantilism, mild finger clubbing, and skin rashes of a deficiency type; (3) megaloblastic change in the bone-marrow; (4) usually free hydrochloric acid in the gastric juice; and (5) defective absorption of fat from the bowel. This syndrome has often been described but only a few patients have been treated with the newer hæmatinics.

The defective fat-absorption may be very difficult to detect and may well be missed unless specially looked for. If it is missed, the diagnosis is likely to be "refractory megaloblastic anæmia." The difficulty is well illustrated by the history of a patient described by Davidson (1948); this man's condition was originally diagnosed as idiopathic refractory megaloblastic anæmia and it responded satisfactorily to folic acid; a year later the patient relapsed, and this time he had fatty bulky stools and his fat-absorption was only 59%; the diagnosis was changed to idiopathic steatorrhœa. In our case 5 the original diagnosis was achrestic anæmia, and it was five years before fatty diarrhœa disclosed the true diagnosis. Clearly, if special attention is paid to fat-absorption, the correct diagnosis may be reached at an earlier stage, and proper treatment will then be started earlier too.

The patients described here illustrate various degrees of difficulty in diagnosis. In case 4 there were alimentary-tract symptoms from the first, and a single four-day fat-balance test revealed the true diagnosis; diagnosis was delayed because originally the patient was thought to have pernicious anæmia on "clinical" grounds, without proper investigation, and because, in view of his age, malignancy had to be excluded. In case 1 a history of abnormal stools was only obtained by direct questioning after our suspicions had been aroused by seeing the stool which the patient regarded as normal; here again, a fat-balance test revealed gross abnormality of absorption. In this case too the infantilism must be emphasised, since it is an important clue. Case 3 presented as a case of infantilism thought to be due to tabes mesenterica. In case 2 there was hardly any overt evidence of steatorrhœa, and a twelve-day fat-balance test was needed to provide the evidence.

The question of what constitutes an adequate fat-balance test was discussed by Fourman et al. (1948); they contended that a twelve-day test is essential for accurate assessment of quantitative changes in fat-absorption. Our experience with case 2 confirms this opinion. A twelve-day test is not easy to arrange, and the technique of daily estimation of fatty-acid excretion, described by Van de Kamer et al. (1949), may perhaps enable the necessary information to be obtained more simply.

The response of these patients to liver extracts, vitamin B_{12}, and folic acids is highly important, not only to the patients themselves but also because of its bearing on the ætiology of megaloblastic anæmias. The current textbook view is that all megaloblastic anæmias are caused by disturbances of the extrinsic-intrinsic factor reaction and the absorption or utilisation of the liver principle so formed. The macrocytic anæmia of tropical and non-tropical steatorrhœa was thought to be brought about by failure of absorption of the liver principle.

There is now sufficient evidence to say that there is a group of cases of megaloblastic anæmia in which the blood picture responds well to liver extracts, vitamin B_{12}, and folic acids; and there is a second group that responds properly to folic acids but not to parenteral liver extracts or to vitamin B_{12} in doses suitable for the first group. Addisonian pernicious anæmia, and nutritional macrocytic anæmia as seen in America and the West Indies, fall into the first group; the second group comprises tropical and non-tropical sprue, "pernicious anæmia" of pregnancy, and possibly most of the patients with nutritional megaloblastic anæmia in other parts of the world. We include tropical sprue because the reports so far published of the action of vitamin B_{12} in tropical sprue, even in West Indian form, are not impressive. For example, Suarez et al. (1949) gave doses of the order of 200 µg. in four or five months, and it was two or three months before the patients' hæmoglobin reached a level of 9 g. per 100 ml.; these are much more like the suboptimal responses to liver extracts than the truly dramatic response often recorded by Spies et al. (1948, 1949a and b) with folic acid.

There is not yet sufficient evidence for a firm explanation to be given of this division of the megaloblastic anæmias, or of the relative parts played by liver factor, vitamin B_{12}, and folic acid in the maintenance of normal erythropoiesis. And there may yet be other factors, because Davidson and Girdwood (1946) and Davidson et al. (1947) have shown that, in some patients with steatorrhœa, the hæmatological response to folic acid, though excellent at first, stops short of normal levels, and then a further rise can be obtained by giving an oral proteolysed liver preparation. Three of our patients have reached reasonable blood levels with folic acid alone, and one needed ascorbic acid as well.

Whatever the explanation, the consequences of this division for the patients are clear. It is more necessary than ever that patients with a suspected "pernicious anæmia" should be properly investigated—by blood-count, bone-marrow study, and fractional test-meal—*before* any treatment with liver, folic acid, or vitamin B_{12}, alone or in combination, is given. If megaloblastic marrow is present and free acid is found in the gastric juice, the next step, irrespective of the gross appearance of the stools or normal values for the fat-content of a single fæcal specimen, should be a fat-balance test. This caution must be extended to those young patients aged 20 or less who have a megaloblastic anæmia with achlorhydria, since true pernicious anæmia is exceedingly rare in this age-group. Only in this way can the best results be achieved and the not very common case detected for which folic acid is the treatment of choice.

SUMMARY

Five cases of idiopathic steatorrhœa (non-tropical sprue) with megaloblastic anæmia are described.

The diagnostic difficulties, particularly the fact that the fat-absorption defect may be missed, are discussed.

The patients were refractory to parenteral liver treatment and showed no response to a dose of vitamin B_{12} sufficient to produce a full remission in pernicious anæmia.

All the patients responded promptly and fully to folic acid given by mouth or parenterally, and so far reasonable blood-counts have been maintained.

One of these patients received the folic acid in the form of a synthetic conjugate, pteroyltriglutamic acid, and the initial response was similar to that of patients who received pteroylglutamic acid itself.

Folic acid will relieve much of the infantilism, and amenorrhœa when this is present, without supplemental endocrine treatment.

The megaloblastic anæmia of non-tropical sprue belongs to the group of liver-resistant folic-acid-responsive anæmias that now includes most of the megaloblastic anæmias apart from addisonian pernicious anæmia.

These investigations were made on patients under the care of Dr. John F. Wilkinson, director of the department, for whose help and criticism we are grateful. We are indebted to Dr. A. H. Holmes for facilities for studying case 3; to Miss A. M. Hain for endocrine estimations: to Mr. H. Varley for fat-estimations; to the nursing staff; and to Messrs. Lederle Ltd. for supplies of folic acid and teropterin.

NORTH MIDDLESEX HOSPITAL

SINCE the introduction of pure substances into the therapy of anæmias with a megaloblastic bone-marrow considerable interest has been taken in the response of cases to them. Cartwright and Wintrobe (1949) have divided the various macrocytic megaloblastic anæmias into two types: (1) those which respond to the anti-pernicious-anæmia factor in purified liver extracts and to pteroyl-γ-glutamic or folic acid; and (2) those which respond to folic acid alone. The first group comprises Addison's anæmia, sprue, non-tropical nutritional macrocytic anæmia, macrocytic anæmia associated with gastro-intestinal resections, megaloblastic anæmia of infancy, and macrocytic anæmia caused by *Diphyllobothrium latum*. The second includes achrestic anæmia, megaloblastic anæmia of pregnancy, tropical macrocytic anæmia, and refractory megaloblastic anæmia.

Ungley (1949) distinguishes between megaloblastic anæmias which are associated with gastric atrophy and those which are not. In cases with gastric atrophy vitamin B_{12} is as effective as liver extract, and folic acid is only temporarily or partially effective; whereas in cases with no gastric atrophy folic acid is effective in small doses and vitamin B_{12} is ineffective.

The following cases of idiopathic steatorrhœa are reported because they did not respond to adequate dosage of a preparation of vitamin B_{12} known to be active in cases of Addison's anæmia but they recovered promptly with ordinary doses of folic acid. It is of interest that the commercial preparations of vitamin B_{12} are advertised as effective in the anæmia of the related condition, sprue.

CASE-RECORDS

Case 1.—A housewife, aged 25, in her third pregnancy, was admitted to the North Middlesex Hospital eight days before the expected date of delivery because albumin was found in her urine. The first pregnancy had produced a living child at forty weeks, but her second baby had died two months after delivery at thirty-six weeks. The mother's blood was group A, rhesus-positive. She said she had always been anæmic and had taken 'Fersolate' tablets as a routine in all three pregnancies, though apparently laboratory tests of her blood were not done during the pregnancies or at other times. She had *never noticed* any diarrhœa.

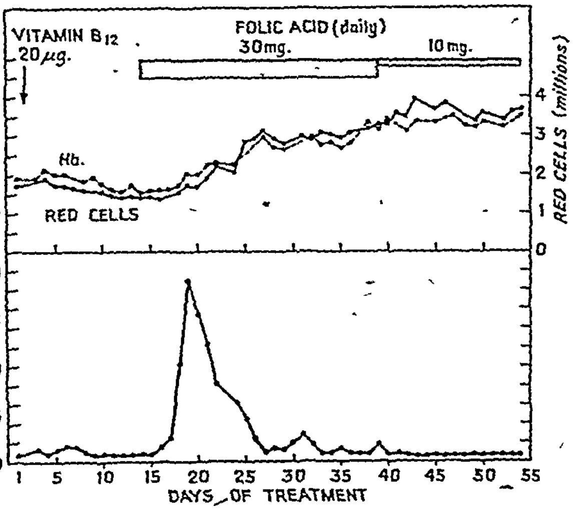

Fig. 1—Blood picture and results of treatment in case 1.

Labour was induced, on the day after admission, by artificial rupture of the membranes, and the placenta was expressed from the cervix under thiopentone anæsthesia. Labour lasted three and a half hours, and 48 oz. of blood was estimated to have been lost. The first blood-count, two days after delivery, showed 1,560,000 red cells per c.mm., Hb 34% (Haldane), colour-index (C.I.) 1·1, mean cell diameter (M.C.D.) 7·8 μ, mean cell volume (M.C.V.) 92 c.μ, and mean corpuscular hæmoglobin concentration (M.C.H.C.) 25%; 6300 white cells per c.mm. (polymorphs 84%, lymphocytes 16%). A transfusion of the packed cells from 880 ml. of compatible blood of group A was given, but three days later the Hb was only 40%. Ten days later it was 38%, though the patient had been receiving gr. 135 of iron and ammonium citrate daily by mouth. Her temperature was 102·4°F seven hours after transfusion, and this was thought to be a transfusion reaction, but neither jaundice nor hæmoglobinuria was found. The sternal marrow was megaloblastic (Israëls 1939), and free hydrochloric acid was found in the gastric juice without histamine stimulation. At this stage no physical signs were present except a sore and smooth tongue.

Treatment and Progress.—The patient was given vitamin B_{12} 20 μg. intramuscularly, but at the end of thirteen days there was no reticulocytosis and no rise in the cell-count or Hb and the bone-marrow was still megaloblastic. The patient remarked that her tongue was no longer sore. At this stage a blood-count showed 1,310,000 red cells per c.mm. and Hb 31%. The reticulocytes had been counted daily and were never more than 1%. The patient was then given folic acid 30 mg. daily by mouth. On the fifth day she had a peak reticulocytosis of 18·8%, and after twenty-four days of this treatment a blood-count showed 3,240,000 red cells per c.mm. and Hb 64%. The bone-marrow was normoblastic fourteen days after the start of the folic acid. On the twenty-fourth day the dose of folic acid was reduced to 10 mg. daily by mouth, and the patient was discharged thirteen days later with Hb 70% and 3,690,000 red cells per c.mm. A four-day fat-absorption test showed only 88·2% absorption. The blood-sugar curve was low and flat. The blood picture and results of treatment are shown in fig. 1.

Case 2.—A married woman, aged 30, was first seen in the outpatient department of the North Middlesex Hospital in August, 1948, when she was complaining of five or six months' pallor and two weeks' soreness of the tongue. She also had dyspepsia, which began soon after meals, and she had lost weight. Her bowels were regular, and there was no diarrhœa. Her menstrual periods were also regular, lasting 4–5 days every 28 days. She had had one child six years previously and no miscarriages. She said she had always been anæmic since adolescence. A blood-count showed 3,780,000 red cells per c.mm., Hb 64%, and C.I. 0·85. Of three stools examined for occult blood the first gave a weak positive and the others were negative. She was given fersolate gr. 6 t.d.s. and one 'Multivite' tablet t.d.s. and asked to return, but she did not keep the appointment. She attended her private doctor

4,620,000 per c.mm. and Hb 14·8 g. per 100 ml. The patient has since kept up a normal blood-count and has been satisfactorily carried through a pregnancy without relapse, a full-term child being born in July, 1949. More details of her blood-counts are given in the table.

DISCUSSION

The syndrome described here is characterised by (1) a progressive and often severe anæmia; (2) infantilism, mild finger clubbing, and skin rashes of a deficiency type; (3) megaloblastic change in the bone-marrow; (4) usually free hydrochloric acid in the gastric juice; and (5) defective absorption of fat from the bowel. This syndrome has often been described but only a few patients have been treated with the newer hæmatinics.

The defective fat-absorption may be very difficult to detect and may well be missed unless specially looked for. If it is missed, the diagnosis is likely to be "refractory megaloblastic anæmia." The difficulty is well illustrated by the history of a patient described by Davidson (1948); this man's condition was originally diagnosed as idiopathic refractory megaloblastic anæmia and it responded satisfactorily to folic acid; a year later the patient relapsed, and this time he had fatty bulky stools and his fat-absorption was only 59%; the diagnosis was changed to idiopathic steatorrhœa. In our case 5 the original diagnosis was achrestic anæmia, and it was five years before fatty diarrhœa disclosed the true diagnosis. Clearly, if special attention is paid to fat-absorption, the correct diagnosis may be reached at an earlier stage, and proper treatment will then be started earlier too.

The patients described here illustrate various degrees of difficulty in diagnosis. In case 4 there were alimentary-tract symptoms from the first, and a single four-day fat-balance test revealed the true diagnosis; diagnosis was delayed because originally the patient was thought to have pernicious anæmia on "clinical" grounds, without proper investigation, and because, in view of his age, malignancy had to be excluded. In case 1 a history of abnormal stools was only obtained by direct questioning after our suspicions had been aroused by seeing the stool which the patient regarded as normal; here again, a fat-balance test revealed gross abnormality of absorption. In this case too the infantilism must be emphasised, since it is an important clue. Case 3 presented as a case of infantilism thought to be due to tabes mesenterica. In case 2 there was hardly any overt evidence of steatorrhœa, and a twelve-day fat-balance test was needed to provide the evidence.

The question of what constitutes an adequate fat-balance test was discussed by Fourman et al. (1948); they contended that a twelve-day test is essential for accurate assessment of quantitative changes in fat-absorption. Our experience with case 2 confirms this opinion. A twelve-day test is not easy to arrange, and the technique of daily estimation of fatty-acid excretion, described by Van de Kamer et al. (1949), may perhaps enable the necessary information to be obtained more simply.

The response of these patients to liver extracts, vitamin B_{12}, and folic acids is highly important, not only to the patients themselves but also because of its bearing on the ætiology of megaloblastic anæmias. The current textbook view is that all megaloblastic anæmias are caused by disturbances of the extrinsic-intrinsic factor reaction and the absorption or utilisation of the liver principle so formed. The macrocytic anæmia of tropical and non-tropical steatorrhœa was thought to be brought about by failure of absorption of the liver principle.

There is now sufficient evidence to say that there is a group of cases of megaloblastic anæmia in which the blood picture responds well to liver extracts, vitamin B_{12}, and folic acids; and there is a second group that responds properly to folic acids but not to parenteral liver extracts or to vitamin B_{12} in doses suitable for the first group. Addisonian pernicious anæmia, and nutritional macrocytic anæmia as seen in America and the West Indies, fall into the first group; the second group comprises tropical and non-tropical sprue, "pernicious anæmia" of pregnancy, and possibly most of the patients with nutritional megaloblastic anæmia in other parts of the world. We include tropical sprue because the reports so far published of the action of vitamin B_{12} in tropical sprue, even in West Indian form, are not impressive. For example, Suarez et al. (1949) gave doses of the order of 200 µg. in four or five months, and it was two or three months before the patients' hæmoglobin reached a level of 9 g. per 100 ml.; these are much more like the suboptimal responses to liver extracts than the truly dramatic response often recorded by Spies et al. (1948, 1949a and b) with folic acid.

There is not yet sufficient evidence for a firm explanation to be given of this division of the megaloblastic anæmias, or of the relative parts played by liver factor, vitamin B_{12}, and folic acid in the maintenance of normal erythropoiesis. And there may yet be other factors, because Davidson and Girdwood (1946) and Davidson et al. (1947) have shown that, in some patients with steatorrhœa, the hæmatological response to folic acid, though excellent at first, stops short of normal levels, and then a further rise can be obtained by giving an oral proteolysed liver preparation. Three of our patients have reached reasonable blood levels with folic acid alone, and one needed ascorbic acid as well.

Whatever the explanation, the consequences of this division for the patients are clear. It is more necessary than ever that patients with a suspected "pernicious anæmia" should be properly investigated—by blood-count, bone-marrow study, and fractional test-meal—*before* any treatment with liver, folic acid, or vitamin B_{12}, alone or in combination, is given. If megaloblastic marrow is present and free acid is found in the gastric juice, the next step, irrespective of the gross appearance of the stools or normal values for the fat-content of a single fæcal specimen, should be a fat-balance test. This caution must be extended to those young patients aged 20 or less who have a megaloblastic anæmia with achlorhydria, since true pernicious anæmia is exceedingly rare in this age-group. Only in this way can the best results be achieved and the not very common case detected for which folic acid is the treatment of choice.

SUMMARY

Five cases of idiopathic steatorrhœa (non-tropical sprue) with megaloblastic anæmia are described.

The diagnostic difficulties, particularly the fact that the fat-absorption defect may be missed, are discussed.

The patients were refractory to parenteral liver treatment and showed no response to a dose of vitamin B_{12} sufficient to produce a full remission in pernicious anæmia.

All the patients responded promptly and fully to folic acid given by mouth or parenterally, and so far reasonable blood-counts have been maintained.

One of these patients received the folic acid in the form of a synthetic conjugate, pteroyltriglutamic acid, and the initial response was similar to that of patients who received pteroylglutamic acid itself.

Folic acid will relieve much of the infantilism, and amenorrhœa when this is present, without supplemental endocrine treatment.

The megaloblastic anæmia of non-tropical sprue belongs to the group of liver-resistant folic-acid-responsive anæmias that now includes most of the megaloblastic anæmias apart from addisonian pernicious anæmia.

These investigations were made on patients under the care of Dr. John F. Wilkinson, director of the department, for

From a review of reported cases it appears that cases of megaloblastic anæmias of pregnancy and refractory cases of megaloblastic anæmia with free gastric hydrochloric acid have not been generally investigated for the presence of idiopathic steatorrhœa.

Acknowledgment is due to Dr. R. Kempthorne for permission to investigate case 2, and to Glaxo Laboratories Ltd. for supplies of vitamin B_{12}.

THE ACTION OF BENZODIOXANE IN MAN

AN EXPERIMENTAL INVESTIGATION

F. T. G. Prunty
M.D. Camb., M.R.C.P.
READER IN CHEMICAL PATHOLOGY AND PHYSICIAN TO ST. THOMAS'S HOSPITAL, LONDON

H. J. C. Swan
M.B. Lond., M.R.C.P.

With a note on negative benzodioxane test

G. M. Wilson
M.B., B.Sc. Edin., F.R.C.P.E., M.R.C.P.
ASSISTANT, MEDICAL UNIT, ST. MARY'S HOSPITAL MEDICAL SCHOOL, LONDON

In 1947 Goldenberg et al. described a test for hypertension due to circulating adrenaline, based on the reversal of the adrenaline pressor effect by the adrenolytic benzodioxanes (Fourneau and Bovet 1933). They found that the intravenous injection of '933F,' 2-(1-piperidylmethyl)-1 : 4-benzodioxane, abolished or significantly decreased the pressor effect observed during infusions of adrenaline in normal subjects. The blood-pressure usually returned to the "pre-dioxane" level in 10–15 minutes. This effect was also found in patients with phæochromocytoma and hypertension. However, the blood-pressure rose when 933F was given to patients with so-called essential hypertension. These opposite responses differentiate the rare phæochromocytoma from the common essential hypertension, and the intravenous injection of 933F has been applied as a clinical test for phæochromocytoma by Goldenberg and his colleagues and by Cahill (1948). Dana and Calkins (1949) report two "positive reactions"—i.e., a fall in blood-pressure—in 67 patients with sustained hypertension. One of these positive reactions was obtained in a patient with phæochromocytoma, but the other occurred in a patient with a neuroblastoma of the adrenal gland, and this was considered to be a false positive.

From our experience with intravenous infusions of adrenaline it appeared to us, as it had to Goldenberg and Aranow (1949), that their pressor effect was not comparable with the hypertension resulting from phæochromocytoma. We found it unusual for circulating adrenaline to raise the diastolic pressure, much less to raise it to levels commonly seen in paroxysmal hypertension due to adrenal tumours. Holton (1949) and Goldenberg et al. (1949) extracted noradrenaline from cases of adrenal medullary tumour, and it therefore seemed that noradrenaline rather than adrenaline might perhaps be the cause of the hypertension in this condition. Hence it became necessary to investigate the effect of dioxane 933F on noradrenaline hypertension, which consists of a rise in systolic and diastolic pressures due to increased peripheral resistance (Goldenberg et al. 1948) and is very similar to that seen in paroxysmal hypertension due to phæochromocytoma.

The experiments described here were planned to contrast the effect of the dioxane on hypertension produced by adrenaline in normal subjects with that produced by noradrenaline, and to observe the resultant circulatory changes by measuring the flow of blood in the calf and the hand by venous-occlusion plethysmography. One might expect to find, perhaps, a vasodilatation in muscle or skin accompanying the fall in blood-pressure.

EXPERIMENTAL

The subjects were men between the ages of 22–45 and were, so far as is known, normal in every respect. They came to the laboratory and rested for an hour before any experimental procedure was undertaken.

An air-filled plethysmograph was then applied to the right calf and another to the right hand. A sphygmomanometer cuff was fitted to the left forearm. A 16-gauge needle was inserted into a vein in the right forearm, and an infusion of physiological saline was started through 'Polythene' tubing sealed to the needle. The capacity of the tubing was about 1·5 ml. Basal estimations of blood-pressure, pulse-rate, and blood-flow in hand and calf were then made while the saline infusion was running. When reasonable stability had been achieved, the required drug (adrenaline or noradrenaline) was continuously infused through the same tubing and needle. The concentration required was delivered in 4 ml. of saline solution per minute. After 20 minutes, by which time the circulatory effects were usually reasonably stable, 933F 0·25 mg. per kg. of body-weight was administered. In 5 cases the injection was made into a small rubber tube interposed between the syringe and the polythene tubing. In 2 cases (subjects 1 and 6) the injection was made directly into another vein in the same arm. The injection was made slowly, being completed in 2 minutes. The changes in blood-pressure and pulse-rate were observed at $^1/_2$-minute intervals, and the changes in limb blood-flow were estimated at $^1/_4$-minute intervals for the next few minutes. Observations were then made at minute intervals for about 15 minutes, after which the infusion of adrenaline or noradrenaline was stopped.

We are indebted to Mr. A. J. Ewins, D.SC., F.R.S., of May & Baker Ltd., for the supply of 933F and for investigating its properties after sterilisation by various methods. He reports that the batch from which our sample was supplied fulfilled the known properties of 933F. Autoclaving at 120°C for half an hour neither caused chemical changes in the compound nor affected its spasmolytic properties.

RESULTS OF INJECTING 933F INTRAVENOUSLY IN PERSONS RECEIVING INFUSIONS OF ADRENALINE OR NORADRENALINE

* Noradrenaline infusion discontinued just after the dioxane injection.

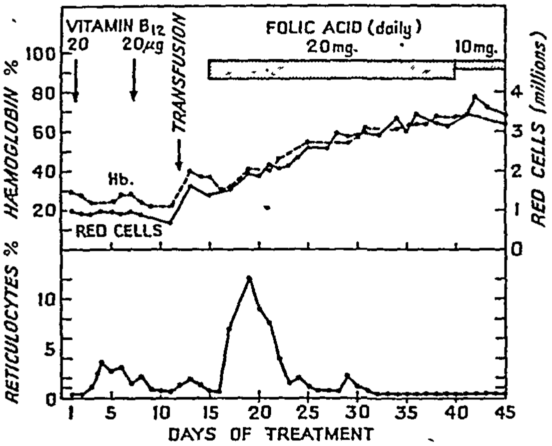

Fig. 2—Blood picture and results of treatment in case 2.

and was given several short courses of iron tablets, but this treatment had been discontinued for about six months before she again came to hospital in October, 1949, fourteen months after the first attendance. She now complained of two months' increasing shortness of breath with tiredness and weakness of the legs.

A blood-count (Oct. 10) now showed 1,080,000 red cells per c.mm., Hb 34%, C.I. 1·5, P.C.V. 17%, M.C.D. 8·4 μ, M.C.V. 140 c.μ, and M.C.H.C. 28%. The patient was pale, with a yellowish tinge of the skin and sclerotics and pallor of the mucosæ. Her nails were brittle but not spoon-shaped, and her tongue was pale and smooth. There was no œdema, and the liver and spleen were not enlarged. The central nervous system showed no abnormality beyond sluggish knee-jerks. The sternal marrow was megaloblastic, with the granulocyte series showing the changes associated with pernicious anæmia. A fractional test-meal gave a normal free-acid curve, and histamine provoked a well-marked response.

Treatment and Progress.—On Oct. 19 (day 1 in fig. 2) a blood-count showed 930,000 red cells per c.mm., Hb 29%, and reticulocytes less than 1%. The patient was given 20 μg. of vitamin B_{12} intramuscularly, and though there was a slight reticulocyte rise on the fourth day (3·5%) there was no appreciable change in the hæmoglobin or red cells. On the seventh day she was given a further 20 μg. of vitamin B_{12} of proved potency, but no response was obtained, and since on the thirteenth day a blood-count showed only 730,000 red cells per c.mm., Hb 22%, and less than 1% reticulocytes it was concluded that none could be expected.

At this time there was some filling of the neck veins, and transfusion was thought necessary. Packed cells from 2 pints of blood were given slowly over eight hours, and next day the red-cell count was 2,100,000 per c.mm. and Hb 40%. A course of folic acid 20 mg. daily by mouth was started, and the reticulocytes reached a peak of 12·5% on the fifth day. This dose was maintained for twenty-five days, by which time the red-cell count had risen to 3,320,000 per c.mm. and Hb to 66%. The patient was discharged six days later on a maintenance dose of 10 mg. of folic acid daily and with a normoblastic marrow.

In view of the findings in case 1, a four-day fat-absorption test was done, which showed only 80% absorption. The blood-sugar curve was flat. The blood-calcium was 9·2 mg. per 100 ml.

DISCUSSION

Idiopathic steatorrhœa was diagnosed in both of these cases although neither patient had ever had diarrhœa. The fat-balance test in both cases was carried out on an intake of 70 g. of fat daily, and the fæces were collected over a four-day period. Cooke et al. (1946) regard absorption of less than 95% as definitely abnormal. They gave 50 g. of fat daily and collected the fæces over a four-day period. Of their 29 cases of idiopathic steatorrhœa 4 had fat-absorption figures of about 90% (cf. case 1, in which the figure was 88·2%). Fourman et al. (1948), giving 70 g. of fat daily, state that fat-excretion over a period of four days has a coefficient of variation of about 30%, but they agree that such a technique is sufficiently accurate for the diagnosis of idiopathic steatorrhœa. The glucose-tolerance curves in cases 1 and 2 strongly support this diagnosis.

Before these tests were done, case 1 was regarded as pernicious anæmia of pregnancy occurring post partum. Since the diagnosis of pernicious anæmia of pregnancy was put on a firm basis by the introduction of sternal puncture, several workers have noticed that some cases are refractory to massive liver therapy (Ungley 1938, Ritter and Crocker 1939, Nielsen 1941). Davidson et al. (1942) reported 16 cases, of which 10 were refractory to liver, and Fullerton (1943) found that 2 cases, out of 3 which gave a reticulocyte response to parenteral liver extracts, showed no improvement in their blood-counts until whole liver or oral extracts were given, and then there was a second reticulocytosis. He drew an analogy with cases of idiopathic steatorrhœa. Davidson et al. (1948) described 3 cases of pernicious anæmia of pregnancy and 1 of Addison's anæmia which relapsed in pregnancy, and of these the case of Addison's anæmia and 2 of the cases of pernicious anæmia of pregnancy gave no response to parenteral liver extract but responded promptly to folic acid. Since then 2 cases of pernicious anæmia of pregnancy have been described in America by Bethell et al. (1948) and Day et al. (1949) which did not respond to intramuscular vitamin B_{12} but recovered promptly with small doses of folic acid by mouth. In this country Ungley (1950) has reported 6 cases which did not respond to vitamin B_{12}; they were given 65–80 μg. of vitamin B_{12} without effect but recovered with 2·5 mg. of folic acid by mouth daily.

The possible rôle of malabsorption in the ætiology of pernicious anæmia of pregnancy has been emphasised by Davidson et al. (1948), who mentioned such a case which subsequently turned out to have idiopathic steatorrhœa though diarrhœa had been absent throughout the period of investigation. In the cases published by Davidson et al. (1942) and Callender (1944) this point was not investigated, and the number of cases of idiopathic steatorrhœa among them must remain a matter for speculation. The additional burden of pregnancy would clearly tend to unmask such cases if they were previously latent.

Case 2 had undoubted idiopathic steatorrhœa. From the clinical point of view this diagnosis is insufficiently considered in refractory megaloblastic anæmias and in ostensible cases of Addison's anæmia in which free acid is found in the gastric juice. We have not discovered any published cases similar to ours treated with vitamin B_{12}. Spies et al. (1949) have treated cases of tropical sprue and non-tropical sprue with vitamin B_{12} both parenterally and by mouth. The dosage given has varied, but they state that 100 μg. may be required to give the greatest hæmatological response. The details of absorption of fat and carbohydrate are not reported in their cases, and the relationship to ours remains problematical. Our own samples of vitamin B_{12} were fully active in Addison's anæmia in the dosage given to the present cases—i.e., 20 and 40 μg.

These cases fall into Ungley's second class (see above), gastric atrophy being absent. It would be interesting to examine the response to vitamin B_{12} of cases of idiopathic steatorrhœa with achlorhydria. Cooke et al. (1946) have shown that cases of Addison's anæmia have a normal fat-balance, and it would therefore be possible to distinguish them from idiopathic steatorrhœa even if the other features of Addison's anæmia were absent.

SUMMARY

Two cases of megaloblastic anæmia associated with idiopathic steatorrhœa are described. One of the cases was first diagnosed post partum.

Both cases failed to respond to therapeutic doses of vitamin B_{12} but recovered promptly with folic acid.

From a review of reported cases it appears that cases of megaloblastic anæmias of pregnancy and refractory cases of megaloblastic anæmia with free gastric hydrochloric acid have not been generally investigated for the presence of idiopathic steatorrhœa.

Acknowledgment is due to Dr. R. Kempthorne for permission to investigate case 2, and to Glaxo Laboratories Ltd. for supplies of vitamin B_{12}.

THE ACTION OF BENZODIOXANE IN MAN

AN EXPERIMENTAL INVESTIGATION

F. T. G. Prunty

In 1947 Goldenberg et al. described a test for hypertension due to circulating adrenaline, based on the reversal of the adrenaline pressor effect by the adrenolytic benzodioxanes (Fourneau and Bovet 1933). They found that the intravenous injection of '933F,' 2-(1-piperidylmethyl)-1 : 4-benzodioxane, abolished or significantly decreased the pressor effect observed during infusions of adrenaline in normal subjects. The blood-pressure usually returned to the "pre-dioxane" level in 10–15 minutes. This effect was also found in patients with phæochromocytoma and hypertension. However, the blood-pressure rose when 933F was given to patients with so-called essential hypertension. These opposite responses differentiate the rare phæochromocytoma from the common essential hypertension, and the intravenous injection of 933F has been applied as a clinical test for phæochromocytoma by Goldenberg and his colleagues and by Cahill (1948). Dana and Calkins (1949) report two "positive reactions"—i.e., a fall in blood-pressure—in 67 patients with sustained hypertension. One of these positive reactions was obtained in a patient with phæochromocytoma, but the other occurred in a patient with a neuroblastoma of the adrenal gland, and this was considered to be a false positive.

From our experience with intravenous infusions of adrenaline it appeared to us, as it had to Goldenberg and Aranow (1949), that their pressor effect was not comparable with the hypertension resulting from phæochromocytoma. We found it unusual for circulating adrenaline to raise the diastolic pressure, much less to raise it to levels commonly seen in paroxysmal hypertension due to adrenal tumours. Holton (1949) and Goldenberg et al. (1949) extracted noradrenaline from cases of adrenal medullary tumour, and it therefore seemed that noradrenaline rather than adrenaline might perhaps be the cause of the hypertension in this condition. Hence it became necessary to investigate the effect of dioxane 933F on noradrenaline hypertension, which consists of a rise in systolic and diastolic pressures due to increased peripheral resistance (Goldenberg et al. 1948) and is very similar to that seen in paroxysmal hypertension due to phæochromocytoma.

The experiments described here were planned to contrast the effect of the dioxane on hypertension produced by adrenaline in normal subjects with that produced by noradrenaline, and to observe the resultant circulatory changes by measuring the flow of blood in the calf and the hand by venous-occlusion plethysmography. One might expect to find, perhaps, a vasodilatation in muscle or skin accompanying the fall in blood-pressure.

EXPERIMENTAL

The subjects were men between the ages of 22–45 and were, so far as is known, normal in every respect. They came to the laboratory and rested for an hour before any experimental procedure was undertaken.

An air-filled plethysmograph was then applied to the right calf and another to the right hand. A sphygmomanometer cuff was fitted to the left forearm. A 16-gauge needle was inserted into a vein in the right forearm, and an infusion of physiological saline was started through 'Polythene' tubing sealed to the needle. The capacity of the tubing was about 1·5 ml. Basal estimations of blood-pressure, pulse-rate, and blood-flow in hand and calf were then made while the saline infusion was running. When reasonable stability had been achieved, the required drug (adrenaline or noradrenaline) was continuously infused through the same tubing and needle. The concentration required was delivered in 4 ml. of saline solution per minute. After 20 minutes, by which time the circulatory effects were usually reasonably stable, 933F 0·25 mg. per kg. of body-weight was administered. In 5 cases the injection was made into a small rubber tube interposed between the syringe and the polythene tubing. In 2 cases (subjects 1 and 6) the injection was made directly into another vein in the same arm. The injection was made slowly, being completed in 2 minutes. The changes in blood-pressure and pulse-rate were observed at $^1/_2$-minute intervals, and the changes in limb blood-flow were estimated at $^1/_4$-minute intervals for the next few minutes. Observations were then made at minute intervals for about 15 minutes, after which the infusion of adrenaline or noradrenaline was stopped.

We are indebted to Mr. A. J. Ewins, D.SC., F.R.S., of May & Baker Ltd., for the supply of 933F and for investigating its properties after sterilisation by various methods. He reports that the batch from which our sample was supplied fulfilled the known properties of 933F. Autoclaving at 120°C for half an hour neither caused chemical changes in the compound nor affected its spasmolytic properties.

RESULTS OF INJECTING 933F INTRAVENOUSLY IN PERSONS RECEIVING INFUSIONS OF ADRENALINE OR NORADRENALINE

Subject no.	Age (yr.)	Drug		Blood-pressure (mm. Hg) and pulse-rate (per min.)

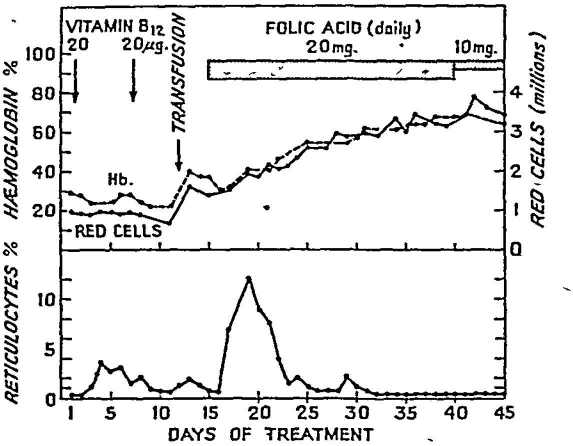

Fig. 2—Blood picture and results of treatment in case 2.

and was given several short courses of iron tablets, but this treatment had been discontinued for about six months before she again came to hospital in October, 1949, fourteen months after the first attendance. She now complained of two months' increasing shortness of breath with tiredness and weakness of the legs.

A blood-count (Oct. 10) now showed 1,080,000 red cells per c.mm., Hb 34%, C.I. 1·5, P.C.V. 17%, M.C.D. 8·4 μ, M.C.V. 140 c.μ, and M.C.H.C. 28%. The patient was pale, with a yellowish tinge of the skin and sclerotics and pallor of the mucosæ. Her nails were brittle but not spoon-shaped, and her tongue was pale and smooth. There was no œdema, and the liver and spleen were not enlarged. The central nervous system showed no abnormality beyond sluggish knee-jerks. The sternal marrow was megaloblastic, with the granulocyte series showing the changes associated with pernicious anæmia. A fractional test-meal gave a normal free-acid curve, and histamine provoked a well-marked response.

Treatment and Progress.—On Oct. 19 (day 1 in fig. 2) a blood-count showed 930,000 red cells per c.mm., Hb 29%, and reticulocytes less than 1%. The patient was given 20 μg. of vitamin B_{12} intramuscularly, and though there was a slight reticulocyte rise on the fourth day (3·5%) there was no appreciable change in the hæmoglobin or red cells. On the seventh day she was given a further 20 μg. of vitamin B_{12} of proved potency, but no response was obtained, and since on the thirteenth day a blood-count showed only 730,000 red cells per c.mm., Hb 22%, and less than 1% reticulocytes it was concluded that none could be expected.

At this time there was some filling of the neck veins, and transfusion was thought necessary. Packed cells from 2 pints of blood were given slowly over eight hours, and next day the red-cell count was 2,100,000 per c.mm. and Hb 40%. A course of folic acid 20 mg. daily by mouth was started, and the reticulocytes reached a peak of 12·5% on the fifth day. This dose was maintained for twenty-five days, by which time the red-cell count had risen to 3,320,000 per c.mm. and Hb to 66%. The patient was discharged six days later on a maintenance dose of 10 mg. of folic acid daily and with a normoblastic marrow.

In view of the findings in case 1, a four-day fat-absorption test was done, which showed only 80% absorption. The blood-sugar curve was flat. The blood-calcium was 9·2 mg. per 100 ml.

DISCUSSION

Idiopathic steatorrhœa was diagnosed in both of these cases although neither patient had ever had diarrhœa. The fat-balance test in both cases was carried out on an intake of 70 g. of fat daily, and the fæces were collected over a four-day period. Cooke et al. (1946) regard absorption of less than 95% as definitely abnormal. They gave 50 g. of fat daily and collected the fæces over a four-day period. Of their 29 cases of idiopathic steatorrhœa 4 had fat-absorption figures of about 90% (cf. case 1, in which the figure was 88·2%). Fourman et al. (1948), giving 70 g. of fat daily, state that fat-excretion over a period of four days has a coefficient of variation of about 30%, but they agree that such a technique is sufficiently accurate for the diagnosis of idiopathic steatorrhœa. The glucose-tolerance curves in cases 1 and 2 strongly support this diagnosis.

Before these tests were done, case 1 was regarded as pernicious anæmia of pregnancy occurring post partum. Since the diagnosis of pernicious anæmia of pregnancy was put on a firm basis by the introduction of sternal puncture, several workers have noticed that some cases are refractory to massive liver therapy (Ungley 1938, Ritter and Crocker 1939, Nielsen 1941). Davidson et al. (1942) reported 16 cases, of which 10 were refractory to liver, and Fullerton (1943) found that 2 cases, out of 3 which gave a reticulocyte response to parenteral liver extracts, showed no improvement in their blood-counts until whole liver or oral extracts were given, and then there was a second reticulocytosis. He drew an analogy with cases of idiopathic steatorrhœa. Davidson et al. (1948) described 3 cases of pernicious anæmia of pregnancy and 1 of Addison's anæmia which relapsed in pregnancy, and of these the case of Addison's anæmia and 2 of the cases of pernicious anæmia of pregnancy gave no response to parenteral liver extract but responded promptly to folic acid. Since then 2 cases of pernicious anæmia of pregnancy have been described in America by Bethell et al. (1948) and Day et al. (1949) which did not respond to intramuscular vitamin B_{12} but recovered promptly with small doses of folic acid by mouth. In this country Ungley (1950) has reported 6 cases which did not respond to vitamin B_{12}; they were given 65–80 μg. of vitamin B_{12} without effect but recovered with 2·5 mg. of folic acid by mouth daily.

The possible rôle of malabsorption in the ætiology of pernicious anæmia of pregnancy has been emphasised by Davidson et al. (1948), who mentioned such a case which subsequently turned out to have idiopathic steatorrhœa though diarrhœa had been absent throughout the period of investigation. In the cases published by Davidson et al. (1942) and Callender (1944) this point was not investigated, and the number of cases of idiopathic steatorrhœa among them must remain a matter for speculation. The additional burden of pregnancy would clearly tend to unmask such cases if they were previously latent.

Case 2 had undoubted idiopathic steatorrhœa. From the clinical point of view this diagnosis is insufficiently considered in refractory megaloblastic anæmias and in ostensible cases of Addison's anæmia in which free acid is found in the gastric juice. We have not discovered any published cases similar to ours treated with vitamin B_{12}. Spies et al. (1949) have treated cases of tropical sprue and non-tropical sprue with vitamin B_{12} both parenterally and by mouth. The dosage given has varied, but they state that 100 μg. may be required to give the greatest hæmatological response. The details of absorption of fat and carbohydrate are not reported in their cases, and the relationship to ours remains problematical. Our own samples of vitamin B_{12} were fully active in Addison's anæmia in the dosage given to the present cases—i.e., 20 and 40 μg.

These cases fall into Ungley's second class (see above), gastric atrophy being absent. It would be interesting to examine the response to vitamin B_{12} of cases of idiopathic steatorrhœa with achlorhydria. Cooke et al. (1946) have shown that cases of Addison's anæmia have a normal fat-balance, and it would therefore be possible to distinguish them from idiopathic steatorrhœa even if the other features of Addison's anæmia were absent.

SUMMARY

Two cases of megaloblastic anæmia associated with idiopathic steatorrhœa are described. One of the cases was first diagnosed post partum.

Both cases failed to respond to therapeutic doses of vitamin B_{12} but recovered promptly with folic acid.

as follows. There is an initial peripheral vasodilatation, shown in skin and muscle by an increase in blood-flow in calf and hand, causing a slight fall in diastolic pressure. Associated with this change there is a tachycardia which may be responsible for a definite increase in cardiac output, restoring the blood-pressure to a level equal to or above that before its administration, despite a continued increased blood-flow in the muscles. We have no direct estimate of the cardiac output, but from the other changes recorded it seems reasonable to assume that cardiac output is increased.

Thus it appears that the injection of the dioxane 933F during an adrenaline infusion in man causes a pronounced vasodilatation, but the subsequent increase in the output of the heart per minute may lead to a further rise in arterial blood-pressure, as seen in our subjects.

In their original paper Goldenberg et al. (1947) investigated this problem in a similar way on a large series of normal people undergoing adrenaline infusions and found that 933F produced a fall in blood-pressure in these circumstances. Moreover, Dr. Goldenberg (personal communication) has recently told us that he has effected a fall in blood-pressure in 12 subjects undergoing infusions of noradrenaline by the injection of 933F. This fall is neither so great nor so sustained as that observed during adrenaline infusions. Therefore there is a considerable weight of experimental evidence to support Goldenberg's contention that 933F can be used to differentiate phæochromocytoma with hypertension from hypertension due to other causes.

In our recent series of normal subjects, however, we did not observe a sustained fall in blood-pressure in any case. Moreover, 5 of the 7 subjects reported distinctly unpleasant symptoms, and subject 6 had a severe reaction to the 933F. The matter has therefore not been pursued so fully as was intended and our series is small. Nevertheless the results are reported as factual observations, however unexpected.

In the clinical application of this test, as previously mentioned, considerable evidence of its positive value has been reported by Goldenberg (personal communication) and by Cahill (1948). However, Dr. G. M. Wilson, in an addendum to this paper, describes briefly a case of proved phæochromocytoma in which the reaction to 933F was the same as in our subjects. A "false positive" has also been reported by Dana and Calkins (1949).

The experimental findings in animals are of limited value in assessing the application of such a test to man, but in the chloralosed vagotomised dog Hermann et al. (1939) showed that infusions of adrenaline after the administration of a large dose of 933F produced a result very similar to that which we observed. On the other hand, Melville (1937) found that, in dogs, 933F reversed the adrenaline pressor effect.

It will be seen that, though there is good evidence of the value of 933F in the diagnosis of phæochromocytoma, there are still some discrepancies in the observed results. How can these be explained? The blood-pressure level is a complex end-response, in so far as it is a product of the cardiac output and the total peripheral resistance. In our subjects we feel that a probable increase in cardiac output more than balanced a pronounced vasodilatation, while in others the reverse may have held good. Further investigation on these points is needed.

SUMMARY

Benzodioxane (933F) was injected intravenously into 7 normal subjects undergoing infusions of adrenaline or noradrenaline.

A fall in blood-pressure lasting a few seconds was succeeded by a rise to a level above that observed before the dioxane was injected.

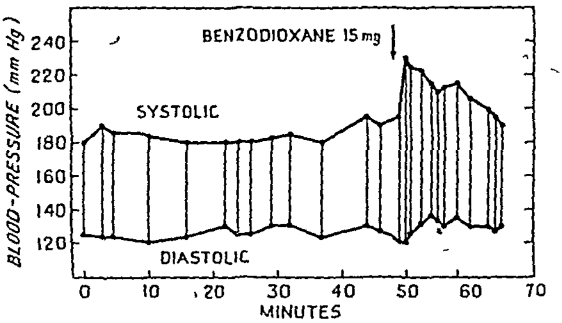

Fig. 3—Rise in systolic pressure, with little change in diastolic pressure when 933F was injected in a patient with a phæochromocytoma of the adrenal gland.

Both the fall in blood-pressure and its subsequent rise were accompanied by tachycardia and vasodilatation in the skin and skeletal muscles.

Unpleasant and alarming symptoms were at times produced.

The significance of these findings, with particular reference to the use of the dioxane effect in the diagnosis of phæochromocytoma, is discussed in relation to the findings of other workers.

ADDENDUM

Two further experiments have been performed using 'Benodaine' brand of 933F (for which we are indebted to Dr. R. C. Pogge of Messrs. Merck & Co., New Jersey). Given during an infusion of adrenaline, benodaine produced an effect in all respects similar to those described above, whereas during an infusion of noradrenaline a fall of systolic pressure of 5–10 mm. Hg occurred during a period of 20 minutes when the infusion was terminated.

Note on Negative Benzodioxane Test

(DR. G. M. WILSON)

A man, aged 38, was admitted to St. Mary's Hospital, under Prof. G. W. Pickering, with 2 years' history of recurrent attacks of pallor, trembling, and sweating. A mass felt below the right costal margin was shown radiologically to be a tumour of the adrenal gland. The blood-pressure was constantly elevated at about 180/120 mm. Hg.

The patient was given an intravenous drip-saline infusion, and his blood-pressure was recorded. After 46 minutes, 15 mg. of 933F (May & Baker) was injected into the tubing, without the patient's knowledge, over a period of 2 minutes. The injection produced a considerable rise in systolic pressure with little change in diastolic pressure (fig. 3), and conspicuous flushing of the face.

Subsequently a phæochromocytoma weighing 45 g. and 5 cm. in diameter, was removed from the patient's right adrenal gland. He has had no further paroxysmal attacks over a period of 15 months, but his arterial pressure has remained elevated.

Full details of this and two other cases of phæochrome tumours of the adrenal gland are to be published later.

RESULTS

In all, 7 experiments were carried out: 4 on subjects undergoing adrenaline infusions and 3 on subjects undergoing noradrenaline infusions. The results are shown in the accompanying table. It was intended to extend the series further, but for reasons described below this was not done.

Adrenaline

Subject 1.—Aged 45. An infusion of 0·03 mg. of adrenaline per minute was needed to raise the systolic blood-pressure 20 mm. Hg. Administration of the dioxane caused a transient fall in systolic pressure, a well-marked tachycardia, and a rise in systolic pressure within 3 minutes of its injection. Thereafter the systolic and diastolic pressures continued to rise gradually until the adrenaline infusion was stopped. The tachycardia abated within 5 minutes but did not settle to the pre-dioxane level until the adrenaline infusion had been discontinued. The subject noticed a flushing of the face and upper chest with a feeling of great heat some 40 seconds after the start of the dioxane injection. He also developed a tremor of his right hand and complained of apprehension.

Subject 2.—Aged 23. The recorded hæmodynamic changes are shown in fig. 1. There were no untoward symptoms.

Noradrenaline

Subject 5.—Aged 23. An infusion of 0·02 mg. of noradrenaline per minute raised the diastolic pressure 15 mm. Hg and the systolic pressure 20 mm. Hg. Administration of the dioxane caused a transient fall in diastolic pressure, with a subsequent rise in systolic pressure to 10 mm. Hg above the noradrenaline level. The bradycardia was abolished, and there was a transient increase in blood-flow in the hand and calf. The major hæmodynamic changes are shown in fig. 2. There was little symptomatic discomfort.

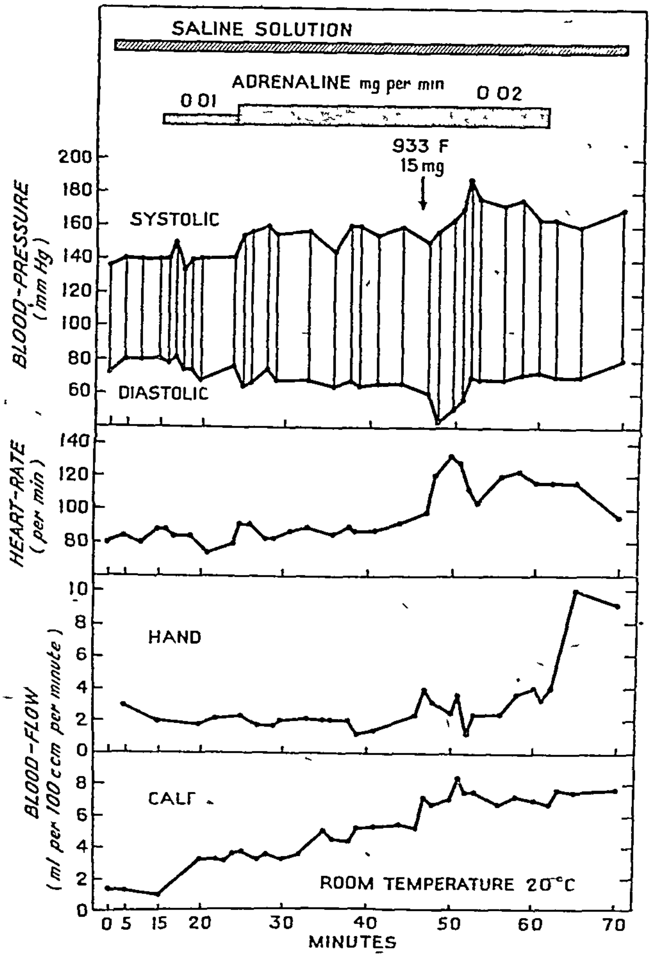

Fig. 1—Blood-pressure, heart-rate, and blood-flow in hand and calf in subject 2, receiving an infusion of adrenal[illegible] solution of adrenaline in saline was subst[illegible] This solution gave a concentration of 0·01 [illegible] later increased to 0·02 mg. per minute. A[illegible] was injected slowly, as described in the text.

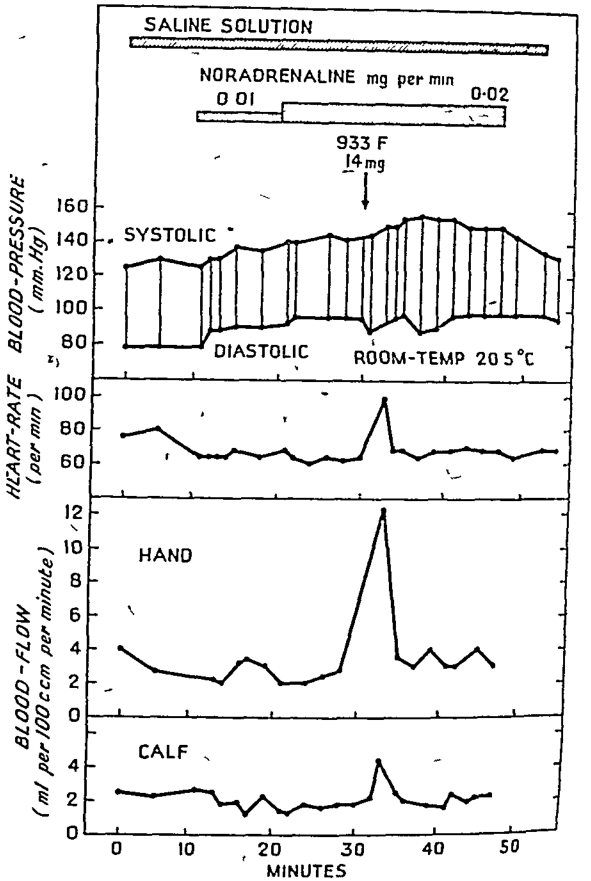

Fig. 2—Blood-pressure, heart-rate, and blood-flow in hand and calf in subject 5, receiving an infusion of noradrenaline. The figure gives the concentration of noradrenaline per minute. At the arrow 14 mg. of 933F was injected in the manner described.

Subject 6.—Aged 27. An infusion of 0·02 mg. of noradrenaline per minute produced a rise in systolic and diastolic pressures which was considered excessive, so the infusion-rate was reduced to 0·01 mg. per minute, which produced an increment of 15 mm. Hg diastolic and 30 mm. Hg systolic. There was the usual bradycardia with a decrease in blood-flow in the calf. When readings had been stabilised benzodioxane was injected slowly, and within 40 seconds the subject noted an unpleasant sensation of warmth on the chest and spreading up into the face; 30 seconds later he appeared to be very distraught (afterwards he said he had felt he was losing consciousness) and started violent involuntary movements with his legs. The injection of dioxane, then about two-thirds complete, was discontinued and the noradrenaline infusion shut off. The subject continued to move his legs for several minutes. Within 30 seconds of the start of the dioxane administration a pulse-rate of 140 per minute was recorded with a fall of diastolic pressure from 100 to 75 mm. Hg and a rise in systolic pressure from 185 to 200 mm. Hg. Owing to the movements of the subject the records of blood-flow in calf and hand at the time were useless. The hypertension persisted for an hour or more after the dioxane had been injected, and the pulse-rate remained between 80 and 90 per minute for that time.

Further investigations were made on patients without cardiovascular abnormality, and it was found that, in the absence of circulating adrenaline or noradrenaline, the injection of 933F in comparable doses produced little if any change in pulse-rate or blood-pressure.

DISCUSSION

The probable sequence of events following the dioxane injection during adrenaline or noradrenaline infusions is as follows. There is an initial peripheral vasodilatation, shown in skin and muscle by an increase in blood-flow in calf and hand, causing a slight fall in diastolic pressure. Associated with this change there is a tachycardia which may be responsible for a definite increase in cardiac output, restoring the blood-pressure to a level equal to or above that before its administration, despite a continued increased blood-flow in the muscles. We have no direct estimate of the cardiac output, but from the other changes recorded it seems reasonable to assume that cardiac output is increased.

Thus it appears that the injection of the dioxane 933F during an adrenaline infusion in man causes a pronounced vasodilatation, but the subsequent increase in the output of the heart per minute may lead to a further rise in arterial blood-pressure, as seen in our subjects.

In their original paper Goldenberg et al. (1947) investigated this problem in a similar way on a large series of normal people undergoing adrenaline infusions and found that 933F produced a fall in blood-pressure in these circumstances. Moreover, Dr. Goldenberg (personal communication) has recently told us that he has effected a fall in blood-pressure in 12 subjects undergoing infusions of noradrenaline by the injection of 933F. This fall is neither so great nor so sustained as that observed during adrenaline infusions. Therefore there is a considerable weight of experimental evidence to support Goldenberg's contention that 933F can be used to differentiate phæochromocytoma with hypertension from hypertension due to other causes.

In our recent series of normal subjects, however, we did not observe a sustained fall in blood-pressure in any case. Moreover, 5 of the 7 subjects reported distinctly unpleasant symptoms, and subject 6 had a severe reaction to the 933F. The matter has therefore not been pursued so fully as was intended and our series is small. Nevertheless the results are reported as factual observations, however unexpected.

In the clinical application of this test, as previously mentioned, considerable evidence of its positive value has been reported by Goldenberg (personal communication) and by Cahill (1948). However, Dr. G. M. Wilson, in an addendum to this paper, describes briefly a case of proved phæochromocytoma in which the reaction to 933F was the same as in our subjects. A "false positive" has also been reported by Dana and Calkins (1949).

The experimental findings in animals are of limited value in assessing the application of such a test to man, but in the chloralosed vagotomised dog Hermann et al. (1939) showed that infusions of adrenaline after the administration of a large dose of 933F produced a result very similar to that which we observed. On the other hand, Melville (1937) found that, in dogs, 933F reversed the adrenaline pressor effect.

It will be seen that, though there is good evidence of the value of 933F in the diagnosis of phæochromocytoma, there are still some discrepancies in the observed results. How can these be explained? The blood-pressure level is a complex end-response, in so far as it is a product of the cardiac output and the total peripheral resistance. In our subjects we feel that a probable increase in cardiac output more than balanced a pronounced vasodilatation, while in others the reverse may have held good. Further investigation on these points is needed.

SUMMARY

Benzodioxane (933F) was injected intravenously into 7 normal subjects undergoing infusions of adrenaline or noradrenaline.

A fall in blood-pressure lasting a few seconds was succeeded by a rise to a level above that observed before the dioxane was injected.

Both the fall in blood-pressure and its subsequent rise were accompanied by tachycardia and vasodilatation in the skin and skeletal muscles.

Unpleasant and alarming symptoms were at times produced.

The significance of these findings, with particular reference to the use of the dioxane effect in the diagnosis of phæochromocytoma, is discussed in relation to the findings of other workers.

ADDENDUM

Two further experiments have been performed using 'Benodaine' brand of 933F (for which we are indebted to Dr. R. C. Pogge of Messrs. Merck & Co., New Jersey). Given during an infusion of adrenaline, benodaine produced an effect in all respects similar to those described above, whereas during an infusion of noradrenaline a fall of systolic pressure of 5–10 mm. Hg occurred during a period of 20 minutes when the infusion was terminated.

Note on Negative Benzodioxane Test

(DR. G. M. WILSON)

A man, aged 38, was admitted to St. Mary's Hospital, under Prof. G. W. Pickering, with 2 years' history of recurrent attacks of pallor, trembling, and sweating. A mass felt below the right costal margin was shown radiologically to be a tumour of the adrenal gland. The blood-pressure was constantly elevated at about 180/120 mm. Hg.

The patient was given an intravenous drip-saline infusion, and his blood-pressure was recorded. After 46 minutes, 15 mg. of 933F (May & Baker) was injected into the tubing, without the patient's knowledge, over a period of 2 minutes. The injection produced a considerable rise in systolic pressure with little change in diastolic pressure (fig. 3), and conspicuous flushing of the face.

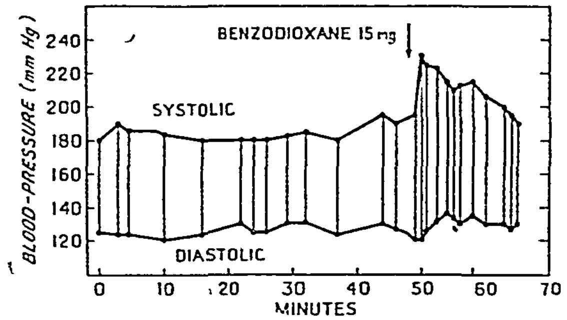

Fig. 3—Rise in systolic pressure, with little change in diastolic pressure when 933F was injected in a patient with a phæochromocytoma of the adrenal gland.

Subsequently a phæochromocytoma weighing 45 g. and 5 cm. in diameter, was removed from the patient's right adrenal gland. He has had no further paroxysmal attacks over a period of 15 months, but his arterial pressure has remained elevated.

Full details of this and two other cases of phæochrome tumours of the adrenal gland are to be published later.

RESULTS

In all, 7 experiments were carried out: 4 on subjects undergoing adrenaline infusions and 3 on subjects undergoing noradrenaline infusions. The results are shown in the accompanying table. It was intended to extend the series further, but for reasons described below this was not done.

Adrenaline

Subject 1.—Aged 45. An infusion of 0·03 mg. of adrenaline per minute was needed to raise the systolic blood-pressure 20 mm. Hg. Administration of the dioxane caused a transient fall in systolic pressure, a well-marked tachycardia, and a rise in systolic pressure within 3 minutes of its injection. Thereafter the systolic and diastolic pressures continued to rise gradually until the adrenaline infusion was stopped. The tachycardia abated within 5 minutes but did not settle to the pre-dioxane level until the adrenaline infusion had been discontinued. The subject noticed a flushing of the face and upper chest with a feeling of great heat some 40 seconds after the start of the dioxane injection. He also developed a tremor of his right hand and complained of apprehension.

Subject 2.—Aged 23. The recorded hæmodynamic changes are shown in fig. 1. There were no untoward symptoms.

Noradrenaline

Subject 5.—Aged 23. An infusion of 0·02 mg. of noradrenaline per minute raised the diastolic pressure 15 mm. Hg and the systolic pressure 20 mm. Hg. Administration of the dioxane caused a transient fall in diastolic pressure, with a subsequent rise in systolic pressure to 10 mm. Hg above the noradrenaline level. The bradycardia was abolished, and there was a transient increase in blood-flow in the hand and calf. The major hæmodynamic changes are shown in fig. 2. There was little symptomatic discomfort.

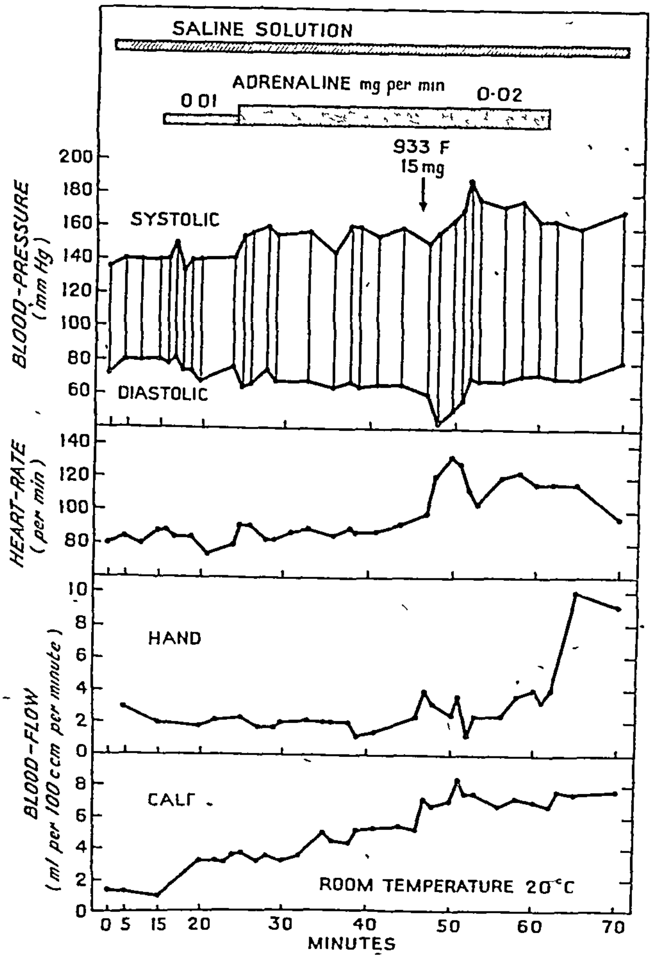

Fig. 1—Blood-pressure, heart-rate, and blood-flow in hand and calf in subject 2, receiving an infusion of adrenaline. At the point indicated a solution of adrenaline in saline was substituted for the saline infusion. This solution gave a concentration of 0·01 mg. of adrenaline per minute, later increased to 0·02 mg. per minute. At the arrow 15 mg. of 933F was injected slowly, as described in the text.

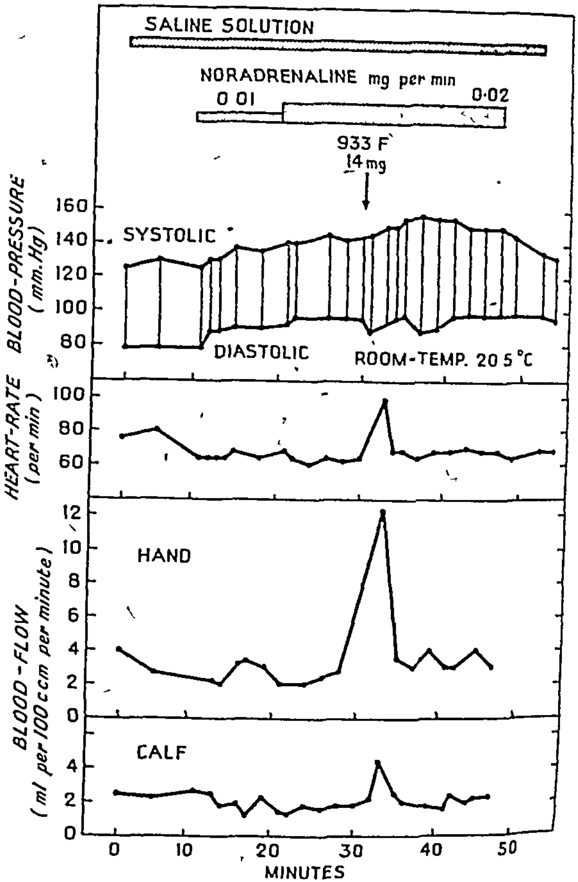

Fig. 2—Blood-pressure, heart-rate, and blood-flow in hand and calf in subject 5, receiving an infusion of noradrenaline. The figure gives the concentration of noradrenaline per minute. At the arrow 14 mg. of 933F was injected in the manner described.

Subject 6.—Aged 27. An infusion of 0·02 mg. of noradrenaline per minute produced a rise in systolic and diastolic pressures which was considered excessive, so the infusion-rate was reduced to 0·01 mg. per minute, which produced an increment of 15 mm. Hg diastolic and 30 mm. Hg systolic. There was the usual bradycardia with a decrease in blood-flow in the calf. When readings had been stabilised benzodioxane was injected slowly, and within 40 seconds the subject noted an unpleasant sensation of warmth on the chest and spreading up into the face; 30 seconds later he appeared to be very distraught (afterwards he said he had felt he was losing consciousness) and started violent involuntary movements with his legs. The injection of dioxane, then about two-thirds complete, was discontinued and the noradrenaline infusion shut off. The subject continued to move his legs for several minutes. Within 30 seconds of the start of the dioxane administration a pulse-rate of 140 per minute was recorded with a fall of diastolic pressure from 100 to 75 mm. Hg and a rise in systolic pressure from 185 to 200 mm. Hg. Owing to the movements of the subject the records of blood-flow in calf and hand at the time were useless. The hypertension persisted for an hour or more after the dioxane had been injected, and the pulse-rate remained between 80 and 90 per minute for that time.

Further investigations were made on patients without cardiovascular abnormality, and it was found that, in the absence of circulating adrenaline or noradrenaline, the injection of 933F in comparable doses produced little if any change in pulse-rate or blood-pressure.

DISCUSSION

The probable sequence of events following the dioxane injection during adrenaline or noradrenaline infusions is

TABLE III—EFFECT OF IODINE TREATMENT ON LACTATION IN FIRST THREE MONTHS

Average birth weight of child (kg.)..	3·14	3·21	3 44	3·44
Average amount of milk taken on 5th day.. ..	200	200	190	193
Breast-feeding twice or more daily:				
No. of mothers feeding for				
3 months	19	22	28	21
2 months	4	1	2	4
1 month	1	0	2	6
Less than 1 month ..	0	1	0	1
Full breast-feeding:				
No. of mothers feeding for				
3 months	7	10	7	3
2 months	6	8	6	7
1 month	4	3	4	5
Less than 1 month ..	7	3	15	17

mother was used only if a "control" mother matching almost perfectly in all respects had been investigated. For this reason a considerable number of records had to be discarded, and the final comparisons were made on about half the women studied. Where possible, the same women were used for all three comparisons. Many mothers went home on the ninth day; hence fewer records were available for the milk yield on that day.

RESULTS

The amounts of milk given by 50 "experimental" mothers on the eighth day and by 23 of them on the ninth day were not significantly different from the amounts given by a like number of controls (tables I and II). The small increases shown by the primiparous women on the eighth and ninth days are not statistically significant (from the fifth to the eighth day: $t = 0{\cdot}30$, $p = 0{\cdot}8\text{–}0{\cdot}7$; from the fifth to the ninth day: $t = 2{\cdot}02$, $p = 0{\cdot}1\text{–}0{\cdot}05$). The multiparous women were inconsistent, the eighth day showing a small increase with iodine treatment which is not significant ($t = 0\ 82$, $p = 0{\cdot}5\text{–}0{\cdot}4$) but the ninth day a decrease.

The later lactation of 56 of the mothers has been analysed to show (1) the number of mothers who could provide two or more feeds a day for periods up to three months, and (2) the number of these mothers who were fully breast-feeding their babies over these periods. The lactation was not affected by the iodine treatment, the apparent improvement shown by the primiparous women being without statistical significance (feeding twice or more per day: no difference between groups; full feeding: $\chi^2 = 1{\cdot}21$, $p = 0{\cdot}3\text{–}0{\cdot}2$). The multiparous women who received iodine did not lactate so well as the controls.

It therefore seems that, under the conditions of this investigation, iodine did not improve lactation.

DISCUSSION

It was unfortunate that the period of iodine treatment had to be so short, but this should have been offset to some extent by the large dosage used. On Robinson's showing some result of the iodine treatment should have been visible by the eighth and ninth days, and it is obvious that a short term of effective treatment would have great advantages. In Robinson's series the average yield of milk, which was 140 g. on the fifth day, rose during iodine treatment to about 310 g. on the eighth day and 340 g. on the ninth; in the present series the average rise in control and experimental groups was from 190–200 g. on the fifth day to about 290 g. on the eighth day and 330 g. on the ninth. This comparison suggests that the effect observed by Robinson might conceivably have been due to chance. If that were so, however, some explanation would really be needed for the very bad lactation in her controls.

Differences in race, physique, state of nutrition, or normal intake of iodine could hardly have been responsible for the different results obtained with English and German mothers. The experience of Nicholson (1948), added to our own, brings us reluctantly to the conclusion that the improvement in lactation reported by Robinson was not caused merely by the administration of iodine.

Our thanks are due to Professor Anselmino, director of the Landesfrauenklinik, for giving us facilities for the investigation. Two members of the staff of the Klinik, Dr. R. A. von Finck and Dr. R. Stewens, helped to examine the women and complete the records.

TRANSILLUMINATION OF WHITLOWS OF THE TERMINAL PHALANX

E. P. SAMUEL
M.D. Manc.
JUNIOR REGISTRAR, ANCOATS HOSPITAL, MANCHESTER

THE diagnosis of infection in the distal part of a finger is usually simple; the difficulty is to determine the presence and precise situation of pus. Local signs, such as loss of pulp resilience and a point of exquisite tenderness, are often late and may indicate the presence of a relatively large slough.

The technique of transilluminating the infected part was developed to detect the initial appearance of pus in early infections which were being treated conservatively, and thus to avoid premature or delayed incisions. It has also proved most valuable in the examination of infected fingers of children, who could not give a precise account of their symptoms and were difficult to examine. The method is probably not original, but the writer has not seen it described in any article or textbook on surgery of the hand.

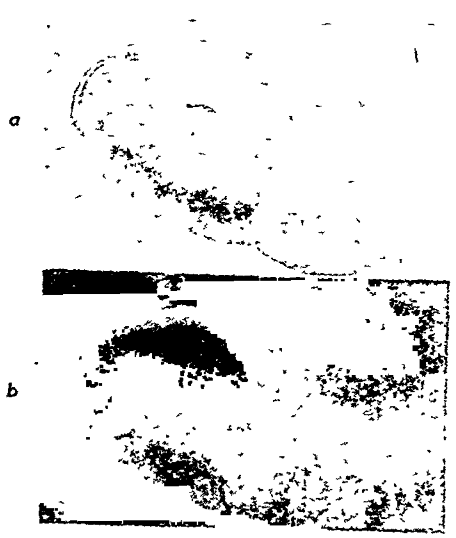

Fig. 1.—Early infection. Shadow cast by pus deeply situated in pulp: *a*, before transillumination; *b*, with transillumination.

IODINE AS AN AID TO LACTATION

R. F. A. DEAN
M.R.C.S.
MEMBER OF MEDICAL RESEARCH COUNCIL SCIENTIFIC STAFF, DEPARTMENT OF EXPERIMENTAL MEDICINE, CAMBRIDGE UNIVERSITY

THE first systematic attempt to use an iodine-containing substance to improve lactation seems to have been made by Hertoghe (1896). According to Robertson (1946), Hertoghe observed that dried thyroid was beneficial to the lactation of women, and he therefore experimented on cows, obtaining increased milk yields. The application of this treatment to domestic animals is discussed by Young (1947).

The thyroid treatment was successfully reapplied to women by Robinson (1947a), working at St. Thomas's Hospital, London, and she later reported (Robinson 1947b) that iodine gave similar good results: 19 of 20 women who had insufficient milk on the fifth day after delivery and who were given a course of Lugol's iodine solution (6 drops twice a day from the sixth to the twelfth day of the puerperium) were able at the end of the course to provide enough milk for unsupplemented feeding; control groups given massage, saline injections, or no treatment gave much less milk. Of the 19 mothers, 8 were seen when their children were aged four weeks, and they were judged, on the basis of two test feeds, to be lactating well. Robinson concluded that one of the causes of failure to establish a satisfactory milk output was a deficiency of iodine. She did not, however, explain how the deficiency arose, or offer any other evidence of its existence.

An attempt to confirm Robinson's claim for iodine treatment was made at Farnborough, in Kent, by Nicholson (1948). He gave Lugol's solution to 19 women but did not find any improvement in their milk yield by the tenth day. He pointed out that the women were receiving other treatment designed to stimulate lactation, and he could not follow their later lactation.

The present investigation was undertaken in the Landesfrauenklinik, Wuppertal, Germany, in 1948. There had been food shortages in the previous years, but conditions had improved and the women were not obviously undernourished. The general standard of lactation was, however, unsatisfactory, and there seemed to be an excellent opportunity to test the value of iodine as a galactagogue.

METHOD

The Landesfrauenklinik was a well-run modern hospital. The importance of breast-feeding was recognised, and a special staff of nurses was maintained to teach the mothers the art of breast-feeding and to care for their breasts. The mothers were strongly encouraged to nurse their babies, but were not given œstrogens or any other medical or physical treatment if the milk-supply was inadequate. The children were always weighed before and after every feed, and the daily yields of milk were obtained in this way.

TABLE I—EFFECT OF IODINE TREATMENT ON MILK YIELD ON EIGHTH DAY

—	Primiparæ		Multiparæ	
	Controls	Experimental	Controls	Experimental
Number in group	22	22	28	28
Average age of mother (years)	26·1	24·0	32·4	32·2
Average birth weight of child (kg.)	3·18	3·20	3·44	3·44
Average amount of milk yield on 5th day (g.) ..	188	185	191	196
Average amount of milk yield on 8th day (g.) ..	302	303	280	297
Average increase in milk yield (g.)	114	118	89	101

Robinson (1947b) showed that successful lactation was unlikely if the milk yield on the fifth day was less than about 280 g., and this criterion was used in the selection of women for the present investigation. Each woman who failed to give 280 g. of milk on the fifth day was interviewed forthwith, and she and her child were examined. A mother was only admitted to the investigation if her home was in the town of Wuppertal and she was hoping to breast-feed the child, if her menstrual history suggested that she had no endocrine abnormality, if the pregnancy had been free from illness, if the delivery had been at full term and unassisted, if the puerperium had been uneventful, and if she and her child were apparently in good health. Half the women so selected were placed in the group for iodine treatment, and the others made up the control group. In 5 women there was a moderate enlargement of the thyroid, but no sign of thyrotoxicosis; 2 of these were given iodine, and the 3 others received no treatment.

It was known that few of the women would stay in the clinic more than eight or nine days after the birth of their children, and that it would be impossible to supervise treatment for the full time advised by Robinson. It was therefore decided to give 12 drops of the iodine solution twice a day—i.e., twice Robinson's dosage—in milk for four days, starting on the morning of the sixth day. If the woman left the clinic before the end of the four days she took the appropriate doses with her. The solution was made by dissolving 10 g. of potassium iodide in 100 ml. distilled water, and then adding 5 g. iodine (both 'Analar' preparations). At first the women in the control groups were given "dummy" milk drinks containing no iodine, but later this practice was discontinued, and nothing was done to balance the psychological stimulus of the iodine treatment.

TABLE II—EFFECT OF IODINE TREATMENT ON MILK YIELD ON NINTH DAY

—	Primiparæ		Multiparæ	
	Controls	Experimental	Controls	Experimental
Number in group	9	9	14	14
Average age of mother (years)	24·2	24·0	32·0	32 8
Average birth weight of child (kg.)	3 09	3·10	3·48	3·53
Average amount of milk yield on 5th day (g.) ..	213	208	184	200
Average amount of milk yield on 9th day (g.) ..	351	366	324	300
Average increase in milk yield (g.)	138	158	140	100

About 100 women were given iodine, and about 100 served as controls. The numbers were greatly reduced, however, before the final analysis of the results.

Three months after the birth of her child each woman in both groups was visited at home and asked about the way in which the child had been fed. The health of the mother and child was also investigated, and the case was discarded if any illness or abnormality was disclosed.

The data have been analysed under three headings: (1) increase in milk yield from the fifth to the eighth day; (2) increase in milk yield from the fifth to the ninth day; and (3) the number of women able to provide full or supplemented breast-feeding at the end of one, two, or three months. For each comparison the "experimental" and "control" mothers were paired as regards the parity and age of the mother, the sex and birth weight of the child, and the amount of milk taken on the fifth day, since all of these might be expected to affect lactation. An "experimental"

SUMMARY

A method of transilluminating terminal whitlows is described which enables the course of the infection to be estimated more accurately than is possible by other means. In this way pus can be precisely located at its earliest appearance, so that a timely and accurate incision can be made.

I wish to thank Mr. P. G. McEvedy, senior surgeon, Ancoats Hospital, and Prof. G. A. G. Mitchell, director of the anatomical laboratories, Manchester University, for their advice, and Miss J. Perry for the illustrations.

Reviews of Books

Happy Toil

Fifty-five Years of Tropical Medicine. Major-General Sir LEONARD ROGERS, K.C.S.I., C.I.E., LL.D., M.D., F.R.C.P., F.R.C.S., F.R.S., I.M.S. retd. London: Frederick Muller. 1950. Pp. 271. 18s.

Sir Leonard Rogers is the doyen of workers in tropical medicine, in the succession of such great figures as Manson, Ross, and Bruce. His activity has been phenomenal and his personal contributions to medical knowledge over a large field have been momentous; indeed, it has been given to few to exert so much influence on the physical welfare of mankind in the torrid climates. Sir Leonard's autobiography, therefore, besides giving an intimate account of the career and personal achievements of a remarkable man, broadly recounts the history of the successful campaign conducted against disease in the tropics for more than half a century. It details the origin of the now world-famous Calcutta School of Tropical Medicine, which owes its inception and subsequent birth to him. If only for these reasons the volume is well worth reading; in addition there is an entertaining account of the conditions of medical education and of professional work of a generation rapidly passing, and of the difficulties that were surmounted by the pioneers of medicine as we now know it

Guide to Diagnosis of Occupational Diseases

Compiled by the staffs of the Industrial Health Division, Department of National Health and Welfare, and the Division of Industrial Hygiene, Department of Health for Ontario. Ottawa: The King's Printer. 1949. Pp. 317. $1.

THE clearness and simplicity of this carefully written Canadian book come from first hand knowledge, hard work, and much revision. It has been compiled by officials of the health departments of the Federal Government and of the State of Ontario, and the authors mainly responsible are Dr. R. B. Sutherland, Dr. E. A. Watkinson, and Mr. H. N. Acker. Their modest intention was "to present only a brief summary of current knowledge of the diagnostic features relevant to occupational diseases," but the result is an outstanding book. They stress, among other things, the importance of taking a full occupational history and of knowing intimately the industrial processes concerned. A list of occupations and their "potential hazards," based on Bulletin No. 41 of the United States Department of Labor, is perhaps the least satisfactory part of the book: it would have been better to indicate the main health risks of each occupation rather than to give long lists of substances, some of them of negligible toxicity, with which the worker might come into contact. But the third and longest chapter, on harmful conditions and substances, is packed full of authoritative and carefully selected information, on which it would be difficult to improve. Nearly all that is worth knowing about industrial medicine and toxicology is adequately and systematically dealt with in 200 pages. The occupational dermatoses are discussed in a short fourth chapter while the fifth and last deals with the Canadian compensation laws. The book will be given free of charge to any doctor in Canada who wishes to have a copy; and doctors in this country may well envy this opportunity. A French edition is also being prepared.

Physiology in Diseases of the Heart and Lungs

M. D. ALTSCHULE, assistant professor of medicine, Harvard Medical School. Cambridge, Mass.: Harvard University Press. London: Oxford University Press. 1949. Pp 368. 40s.

Professor Altschule's team of physicians, surgeons, and radiologists analyse more than 100 cases of cyanotic congenital heart-disease, each dealing with the sections he is best qualified to write on. The embryological survey, though said to be a summary, is a detailed account of the development of the bulb and its adjacent structures, and one of the most comprehensive reviews of this subject so far published. The clinical material is classified into groups, and the symptomatology carefully studied. There are obvious objections to an attempt to group or classify patients' exercise tolerance in relation to the cardiac condition; but the authors try to give an estimate of the severity of the disability. The detailed radiological study is highly instructive, dealing not only with the classical type of Fallot tetralogy but with other associated conditions which have to be distinguished from it. Angiocardiography was freely used, and gave information of great value, as the reproductions of angiocardiograms show. Figures are given showing how cardiac catheterisation may help in diagnosis. Surgical treatment was undertaken in some of the 114 cases investigated, and the difficulties, results, and complications encountered in this series correspond with those described already in larger series from the United States. The detailed case-reports of conditions which do not exactly follow the classical Fallot tetralogy are well worth study by those whose work takes them into this branch.

Diseases of the Aorta

NATHANIEL W. REICH, M.D., associate in medicine, Long Island College of Medicine. New York and London: Macmillan. 1949. Pp. 288. 56s.

THIS monograph appears at an opportune time. The newer methods of investigation of cardiac disease have helped to make surgical treatment possible for some forms of congenital heart-disease, and have roused fresh interest in diseases of the aorta. Dr. Reich has produced a comprehensive and instructive book which will be welcomed by cardiologists as well as general physicians. His style is clear and concise and the numerous illustrations are good, almost without exception. He describes the history, anatomy, embryology, and developmental abnormalities of the aorta, and gives successive chapters to the various aortic diseases, with their symptomatology, diagnosis, and treatment. The last two chapters, on antibiotics and anticoagulants, bring the subject up to the present state of knowledge, and the account of diagnostic procedures strikingly illustrates the progress in scientific methods during recent decades. Some of the methods are treated somewhat perfunctorily—for example, the special tests for determination of the total pulmonary blood-flow, used in the diagnosis of congenital lesions; the early chapters describing congenital abnormalities involving the aorta are by contrast very full, and are particularly well done. It is almost as great a pleasure to handle this book as it is to read it.

Sexual Deviations

L. S. LONDON, M.D.; F. S. CAPRIO, M.D. Washington, D.C.: Linacre Press. 1950. Pp. 702. $10.

THIS is a discussion, illustrated with case-histories, of a number of the classical forms of paraphilia. The approach to psychodynamics and to treatment is strictly psycho-analytical, and the treatment of each recorded case is outlined. The authors summarise the history and some aspects of the social significance of sexual deviation, but without reference to its comparative physiology and psychology. The cases are frequently very instructive, but the proportion which responded to analysis seems high, in terms of British experience; and non-psychiatric readers should perhaps be warned against assuming that all paraphilic symptoms of a given type necessarily arise from the same background as that of the specimen cases. The very wide variety and prevalence of paraphilias in apparently well-adjusted subjects is already

METHOD

The pulp of the finger is transilluminated with the naked bulb of an auriscope. The finger should be cleaned, and, if the patient is a manual worker with thickened epithelium, it can be painted with cedar-wood oil to increase the translucency of the tissues. The bulb is pressed lightly against the finger, which is viewed on the side opposite to the point of illumination. The examination, conducted in a darkened room if possible, is begun on the palmar aspect away from the tender area, the bulb being pressed into the sides and tip of the pulp, and finally against the nail while the pulp is inspected from its palmar aspect. By sliding the light over the finger one can transilluminate each point in turn.

APPEARANCES ON TRANSILLUMINATION

Normal Finger.—The normal pulp on transillumination has a homogenous blood-red appearance, the lunula appearing as a slightly darker area at the base of the nail.

Early Infection.—*In the early stages of infection*, when the patient complains of a pricking or throbbing pain in the finger, it is essential to decide whether the infection is in the pulp tissue, with the possible presence of pus, or a superficial lymphangitis. When the finger is transilluminated in a pulp infection, deep red shadows are visible spreading across the nail which fade and intensify coincidentally with the throbbing experienced by the patient. In a pure lymphangitis, however, the pulsation and the variations in the shadows are less apparent. (Care should be taken not to hold the affected digit too tightly, or the pressure obliterates the digital vessels and the pulsation ceases.) If the treatment adopted is effective and the finger is examined daily, the pulsation shadows diminish in intensity as the inflammation abates, and disappear when the finger returns to normal; but in the event of the infection's proving refractory transillumination reveals the formation of pus as a constant dark shadow (fig. 1) visible against the pulsating background. Pus in the central part of the pulp space is most easily detected if the source of illumination is placed against the nail and the finger-tip is examined from the palmar aspect. Although the clinical signs may be equivocal—i.e., there is no definite point tenderness and the tissues are still resilient—incision into the affected area will demonstrate the presence of pus; should the preliminary incision be unsuccessful, it should be deepened, for pus will be found if its shadow has been seen. In a lymphangitis a constant shadow is never seen.

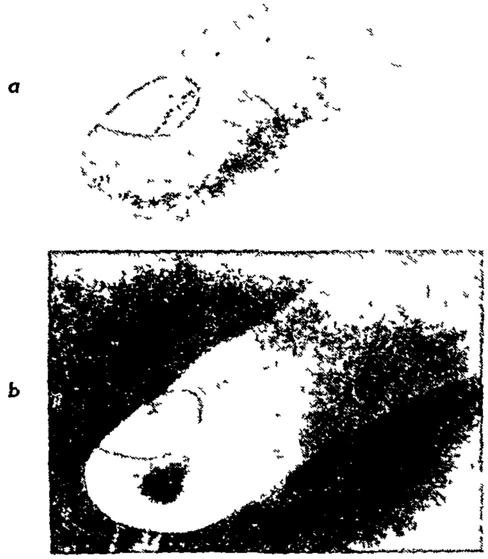

Fig. 2.—Late infection. Sharply demarcated shadow of slough, whose limits can be determined by transillumination: *a*, before transillumination; *b*, with transillumination.

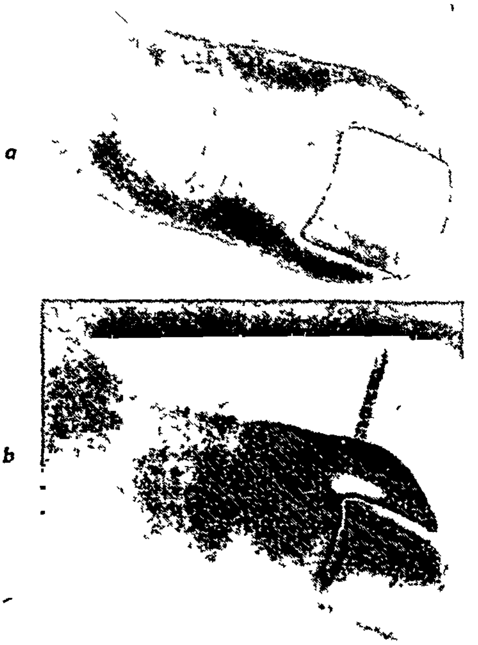

Fig. 3.—Early paronychia developing at side of nail from deep pulp infection: *a*, before transillumination; *b*, with transillumination

Late Infection.—Though pus is obvious clinically, transillumination can be used to demonstrate the precise location and extent of the slough (fig. 2). *If a purulent* blister is present, however, it must be removed *before* transillumination, since its shadow tends to obscure that formed by the deeply situated infection. With the information thus obtained an exact local excision can be made with the minimal trauma and infection of unaffected tissue; this leads to more rapid healing than that which follows routine "hockey-stick" or "fish-mouth" incisions. On occasions a shadow of localised pus without any visible pulsations is observed, indicating the belated success of the patient's defensive mechanism. These lesions heal very quickly when the pus is evacuated.

Paronychia.—To locate subungual pus in a paronychia, any superficial blister should be excised; transillumination will then reveal the subungual pus as an irregular shadow at the base of the nail and possibly extending beyond the lunula, indicating that a further radical procedure is required. When an early paronychia is associated with a concomitant pulp infection, the latter can be seen as a dark shadow extending into the pulp when there is little clinical evidence to suggest its presence (fig. 3). In a child with a neglected paronychia and tender swollen finger it is almost impossible, without transillumination, to ascertain whether a pulp infection is present or not; if the pulp is not infected it is clear and without pulsation, but the paronychia throws a deep horse-shoe shadow round the nail. Treatment may then be given in the knowledge that a pulp infection is not being inadvertently missed. A subungual infection at the tip of the finger may clinically simulate a terminal pulp infection, but transillumination reveals a local slough beneath the nail before its presence is demonstrable as a point of maximal tenderness. This makes possible its earliest eradication.

THE LANCET

LONDON: SATURDAY, APRIL 22, 1950

The Megaloblastic Anæmias

UNTIL lately it was assumed that all cases of megaloblastic anæmia—that is, anæmia with classical megaloblastic changes in the bone-marrow—were caused by some disturbance in the supply, absorption, or utilisation of the anti-anæmic principle found in liver extracts. Much ingenuity was expended in fitting the various anæmias into this unitarian plan. Thus tropical megaloblastic anæmias were due, in the main, to actual shortage of the " extrinsic factor " in the food, which, when acted on by the " intrinsic factor " of the gastric juice, formed the liver principle. Pernicious anæmia was caused by failure of the stomach to secrete intrinsic factor. In steatorrhœa the liver principle was formed but not absorbed. The odd cases of achrestic anæmia resulted from some disturbance between the absorption of the principle from the intestine and its utilisation in the bone-marrow. Pernicious anæmia of pregnancy was perhaps due to the demand for liver principle outrunning the supply. The properties of folic acid (pteroylglutamic acid) still supported this unitarian concept, for all megaloblastic anæmias responded to treatment with it, even though its failure to control the neurological changes in pernicious anæmia made it clear that folic acid could not completely reproduce the action of the natural anti-anæmic liver principle. But patients with megaloblastic anæmia and sprue reacted very well to folic acid; the anæmia and the other clinical signs and symptoms remitted dramatically in spite of the fact that fat absorption remained defective. It was remembered that the anæmia of sprue often reacts poorly to liver extracts, particularly to the purified liver extracts that are so useful in pernicious anæmia. The idea therefore arose that megaloblastic marrow might be transformed to normoblastic marrow by more than one agent; and perhaps that the megaloblastic anæmias themselves were due to a deficiency or failure of action of more than one factor.

This possibility that the megaloblastic anæmias are not all variations on one ætiological theme has received support from recent work on vitamin B_{12}. In this issue Dr. ISRAËLS and Dr. SHARP of Manchester describe 5 cases, and Dr. TUCK and Dr. WHITTAKER of the North Middlesex Hospital 2 cases, of idiopathic steatorrhœa with megaloblastic anæmia that did not respond to vitamin B_{12} but responded fully and completely to folic acid. The Manchester patients had also been refractory to the parenteral liver extracts used for pernicious anæmia, and one had relapsed while being treated with an oral proteolysed liver preparation; it was shown that these patients could be kept in normal health by the regular administration of folic acid, without any other factor. A similar failure to respond to vitamin B_{12} and success with folic acid has been reported in " pernicious anæmia of pregnancy." Furthermore, as we have noted before, the response of tropical sprue to vitamin B_{12} has not been in any way so striking as its response to folic acid. Reviewing what little has been written on this subject, ISRAËLS and SHARP conclude that there is enough evidence to divide the megaloblastic anæmias into two groups. The first group is typified by addisonian pernicious anæmia, and the reports of SPIES and his co-workers place the nutritional megaloblastic anæmias of the southern U.S.A. and the West Indies in this group; the anæmia of these patients responds well to parenteral or oral liver preparations, vitamin B_{12}, and folic acid. The second group includes pernicious anæmia of pregnancy, the megaloblastic anæmia of non-tropical sprue (idiopathic steatorrhœa), and probably tropical sprue as well; these patients respond sharply to folic acid, but not at all, or disappointingly and with large doses only, to liver preparations and vitamin B_{12}. Reports on nutritional megaloblastic anæmia from parts of the world other than America are not yet clear, but it seems likely that they too will fall into the second group. The theoretical implications of this division are difficult to foresee until we have more evidence. Why cannot vitamin B_{12} transform the megaloblastic hyperplasia of idiopathic steatorrhœa to normoblastic, when it can produce this effect on the seemingly morphologically identical megaloblasts of pernicious anæmia? It is far from clear that patients with steatorrhœa have any deficiency of folic acid in their diet; and, since the folic acid is active by mouth in free or conjugated form, defective absorption is unlikely to be the only factor. Is it possible that the action of folic acid on megaloblasts is really non-specific and fortuitous? No new evidence has been brought forward to support the view that deficiency of folic acid plays any part in the ætiology of pernicious anæmia: it may be that in steatorrhœa, too, folic acid is producing the desired effect but that the real defect concerns some other factor.

The classification of the megaloblastic anæmias is in the melting-pot. But fortunately the practical therapeutic lessons of these new observations are quite clear. For true pernicious anæmia, liver extracts, or vitamin B_{12} are the proper materials for treatment; for pernicious anæmia of pregnancy and idiopathic steatorrhœa with megaloblastic (but not with normoblastic) marrow, folic acid is the treatment of choice. The case-records from Manchester and from the North Middlesex Hospital show, however, that the diagnosis of idiopathic steatorrhœa is not easily made and is likely to be missed in these cases unless specifically looked for. The truly heartening results obtained with the correct treatment in these young patients repay all the trouble taken in diagnosis. The distinguishing of these treatable syndromes makes diagnosis before treatment even more essential. The doctor who gives liver, folic acid, or vitamin B_{12} to an uninvestigated case of anæmia may delay proper diagnosis for years; and, since steatorrhœa often affects patients about puberty, the consequences of delay may be irreparable. The doctor will be safer too if in treating anæmias he avoids the blunderbuss remedy, which may have almost as unpredictable an effect as the firearm of the same name.

becoming recognised, and further information about their significance as tokens of neurosis is badly needed: in all the cases here cited there was either manifest conflict in other fields, or some measure of sexual disability. In many the presenting symptom was anxiety about the deviant compulsion. It is therefore still difficult to evaluate the relative importance of the process which produced the deviation and the guilt arising from its existence. In the view of the authors, the underlying conflict is the psychotherapist's main concern; and in the absence of accurate statistical data on the prevalence of the various patterns of deviant mating behaviour, the psycho-analytical approach is certainly useful, though the authors' prognoses, particularly in homosexual cases, are rather optimistic. They make sensible suggestions about prophylaxis, medicolegal problems, and the question of sex in prisons. The book is a careful and well-documented contribution to the psycho-analytical treatment of deviation, which workers in this country will welcome. It presents a picture of paraphilia in psychiatry which has yet to be reconciled with the wider biological aspects.

Advances in Surgery

Vol. II. Editor: W. DEW. ANDRUS. New York and London: Interscience Publishers. 1949. Pp. 587. 88*s*.

IN the second volume of this series, Dr. DeWitt Andrus is helped by such people as Hugh Cairns, Clarence Crafoord, and Gordon Murray, as well as a team of distinguished American authors. They consider, among other things, the advances made in surgery of the œsophagus, the heart and great vessels, hypertension, and brain injuries. There is a very good contribution on tumours of the testis by Lloyd G. Lewis, and the place of streptomycin in the treatment of surgical infections is discussed. Other sections are devoted to skin-grafting, the surgery of the pancreas, and tumours of peripheral nerves. Nor is the physiological background forgotten: Riley and Cournand in particular relate the study of pulmonary function to chest surgery. A reasonably comprehensive view is thus given of the development and present position of surgery in these specialised subjects, and no better refresher course on them could be recommended. Even if the specialist surgeon does not find much new in the section dealing with his own interest, there are references in plenty to current work which may add to his knowledge. More explanatory illustrations would be welcome in the next edition.

Histopathology of the Skin

WALTER F. LEVER, M.D., instructor in dermatology, Harvard Medical School. London and Philadelphia: J. B. Lippincott. 1949. Pp. 449. 75*s*.

IN recent years several good handbooks on the histopathology of the skin have been published; but this new one will certainly be useful, especially to those dermatologists who are not also expert pathologists, and to pathologists who have only limited experience of dermatology. The text is lucid, and the illustrations (nearly all in black-and-white) are clear. Dr. Lever knows the limitations of his subject, and insists that histopathological examination can often be only an aid to diagnosis, and will not always give the final answer to a diagnostic problem. Short concise clinical descriptions of the diseases considered are included, and references are full.

Die chemotherapeutische Tamponade der Lungenkavernen

GUSTAV MAURER, Schatzalp/Davos. Stuttgart: Thieme. 1950. Pp. 114. D.M. 18.

IN a comparatively short but well-produced monograph, written in German, Gustav Maurer introduces and shows the results of a technique which he has used in the treatment of certain lung cavities. His principle is an elaboration of cavity drainage, but instead of depending on a fine tube of the Monaldi type he steadily dilates the opening into the cavity up to the size of a finger by means of laminaria tents; through this opening a tube can be introduced, and so can chemotherapeutic agents, notably streptomycin or *p*-aminosalicylic acid. He believes that the action of these agents on the disease in the walls of the cavity helps to eliminate tuberculous infection and favours closure. The cavities chosen for this form of treatment are approached from in front, usually below the level of the clavicle, and some very good results are illustrated. Dr. Maurer sometimes finds it necessary to assist closure of the cavity by a small upper thoracoplastic operation. The bibliography is unduly short and very far from comprehensive.

Hospital Administration for Women (2nd ed. London: Faber. 1950. Pp. 342. 35*s*.).—The first edition of Miss Emily MacManus's book proved of such value to hospital administrators that it is disappointing to find the second edition out of date. Much of the advice given would certainly not do today. The preface is excellent, the principles of administration remain as sound as before, and the care and welfare of the patients are kept before the reader all the time; but the details would be of little value to a newly appointed matron, and the reader cannot help feeling that an opportunity has been lost.

Oxidation-Reduction Potentials in Bacteriology and Biochemistry (6th ed. Edinburgh: E. & S. Livingstone. 1950. Pp. 215. 20*s*.).—The sixth edition of this book follows within two years of the fifth; even so, as Mr. L. F. Hewitt, PH.D., notes in his preface, it has been extensively revised, and three new chapters have been added—on pH determinations, metabolic cycles, and chemotherapeutic agents and antibiotics. The early chapters are still introductory, but encouraged by widely scattered correspondents Dr. Hewitt has broadened his scope, and the later chapters in succeeding editions have dealt increasingly with "the implications and effects of oxidation-reduction conditions in metabolic processes."

Mitchell-Nelson Textbook of Pediatrics (5th ed. Philadelphia and London: W. B. Saunders. 1950. Pp. 1658. 63*s*.).—This outstanding textbook renews itself regularly every four or five years. Prof. Waldo E. Nelson, successor in editorship to the late Dr. Mitchell, has kept his team of contributors hard at it, and Mrs. Nelson has shared in the editing. There are several new, and many rewritten, sections, and the book covers the whole body of pædiatrics which in the last twenty years has grown as inevitably as, but a great deal faster than, a coral island. The accretions do not perhaps receive equal treatment: it is a little startling to find emotional growth and development discussed in less than a page, but some like the mind and some the body, and those editors who remember that the two are one are as rare as cases of phocomelia and ectrodactylia, depicted here. The body receives a handsome tribute throughout.

Diseases Commonly met with in Melanesia (*3rd ed.* New Zealand: Melanesian Mission, Shortland Street, Auckland. 1949. Pp. 100. 7*s*. 6*d*.).—In large print and small compass Dr. Clifford S. James deals with the prevention and treatment of the disease which field workers of the Melanesian Mission—and also residents living beyond the care of a doctor—may encounter. To bring the book up to date on new methods of chemotherapy he has enlisted the help of Dr. A. G. Rutter. He starts each section with the differential diagnosis of a given symptom, displayed clearly on a single page. "If your patient complains especially of fever," the first of these begins, "think of—" and then follows a list, headed by malaria, the most common causes appearing first in black type, the rarer things below in ordinary type. Language throughout is simple and sentences short, and the book must often have done yeoman service in far-off places.

Casualty Faking (British Red Cross Society. 1949. Pp. 36. 4*s*.).—Half the fun of first-aid training comes in learning how to deal with the serious casualty; and however rare the opportunities for doing this may be in ordinary life, vaulting ambition still hopes for the worst. Imagination and a willing friend will do much to prepare the first-aid student for his great opportunity; but a few life-like injuries will add greatly to the sobriety with which he approaches his task. In this little book, Mr. Ernest James Ward, an enthusiast if ever there was one, describes and elegantly illustrates the ways in which horrible injuries may be successfully counterfeited. He teaches the tyro to handle putty, soft paraffin, grease-paints, and mock-blood in a way to curdle the ordinary kind, and ingeniously produces eggshell crackling with *real* eggshell—surely a case of art improving on nature. A most attractive and instructive book, as Sir Harold Whittingham says in a foreword.

hopeless.[14] Their vision is often greatly improved by sympathectomy. Stock[15] and Evans[16] have drawn attention to the particular suitability for sympathectomy of women with hypertension following toxæmia of pregnancy. The difficulty of devising a reliable method of assessing prognosis and the likely response to sympathectomy is stressed by Hinton and Lord.[17] From their experience in 375 cases, with 38 deaths at or within six months of operation, they have drawn up a set of rules for selecting patients for operation. Briefly, they reject patients with renal failure, persistent congestive cardiac failure, recent coronary thrombosis or strokes, mental confusion due to cerebral changes, or less serious vascular damage in several organs. If they had applied these rules they would have rejected 30 of the 38 patients who died, but they would also have turned down 25 patients who in fact did well. The selection of patients is discussed on p. 787 by Professor Wells and Mr. Welbourn and by Mr. Shucksmith, who are impressed by the symptomatic relief which many of the severe cases experience, and by the possibility of complete cure in the early cases.

One defect stands out clearly in all discussions of the treatment of hypertension—our lack of knowledge of the prognosis of cases not treated surgically. Useful surveys have been made[18] but no large series of cases has been published in which the patients have been investigated so completely and followed for so long as those in the surgical series. More data are needed, and it is to be hoped that all physicians and surgeons concerned with the management of hypertensive patients will assess them as completely as possible, make careful follow-up studies, and publish their observations.

Treatment of Herpes Zoster

Zoster is a self-limiting disorder ranging in intensity from a banal painless rash, calling for no treatment other than a shake lotion, to a gangrenous secondarily infected eruption with pain severe and persistent enough to call for the most powerful anodynes. For this reason the assessment of different treatments is even more tricky than in disorders with more uniform natural histories. Even with a controlled series a large number of cases is necessary to eliminate chance, and the statistical study of intensity of pain offers another difficulty. The fairest series for a controlled study in this particular malady would probably be one confined to patients of comparable age-groups with zoster affecting the ophthalmic division of the fifth nerve, a site often severely involved as regards both pain and local reaction.

In the circumstances, it is not to be wondered at that many drugs and physiotherapeutic measures have been reputed to relieve zoster. X-ray therapy to the skin lesions and to the affected dorsal-root ganglia has its advocates. Keichline[19] treated 62 cases in this way, using 148 r through a 3 mm. aluminium filter at a distance of 30 cm.; nine-tenths of his patients were relieved by one exposure, the others requiring one or two additional exposures. Posterior pituitary extract in a daily dose of 1 ml. subcutaneously has been reported[20] to relieve pain and shorten the course, but it cannot be given during pregnancy, and the fact that it is also contra-indicated in patients with cardiovascular disease reduces its scope since many of the worst cases of zoster are in elderly people. The same claim is made for sodium iodide in 20 ml. doses of a 10% solution intravenously on the first, second, fourth, and seventh days of the eruption.[21] Intramuscular injections of contramine (0·125 g.) or of crude liver extract (4 ml.) have seemed to alleviate the pain, and diphtheria antitoxin has been recommended[22] for the resistant ophthalmic type, 5000 units being given and repeated two days later if necessary. More exotic remedies include moccasin venom[23] and cobra venom with sulphanilamide,[24] and even the more homely autohæmotherapy has been credited with good results. Where they are not purely due to suggestion, the effects of many of these remedies may be based on the initiation of a nonspecific foreign-protein reaction. In a different category may be the favourable reports[25] on blood-transfusions from convalescent donors, three weeks to two years after the infection, first advocated by Gunderson.[26]

Lately Finland and his colleagues[27] have treated 24 cases with 'Aureomycin,' starting with 1 g. four times a day and halving the dose if there was definite improvement or if nausea or vomiting were troublesome. Their total dosage varied from 7·5 to 54 g. given over periods ranging from three to seventeen days. There were 19 patients in their series over 50 years of age, but the response to treatment seemed to bear no relation to age. The best results were in patients treated before the middle of the second week, after the first appearance of symptoms or lesions. Rapid evolution and clearing of the eruption usually began within or shortly after the first 24 hours of aureomycin therapy. Even patients with ophthalmic zoster responded favourably. The immediate effect on the pain is said to have been striking, great relief being noted within 24 hours and the relief usually being complete in four or five days. Postherpetic pain occurred in 6 of the patients. Fresh lesions did not develop during aureomycin therapy except in the first day or so, though such lesions might appear if treatment was interrupted too soon. Nevertheless, herpes zoster has first appeared in the course of aureomycin treatment for other infections,[28] and this perhaps suggests that the ætiology of the lesions is not always the same, or that there are differences in the susceptibility of various strains of zoster virus to aureomycin. A similar apparent paradox has been noted with vitamin B in zoster. Given subcutaneously in a dose of 3000 I.U. (1 mg. = 320 I.U.)

Sympathectomy for Hypertension

Sympathectomy has been widely practised in recent years as a treatment for hypertension, and the American clinics have reported results in many hundreds of cases; yet there is little agreement among the authorities on the indications for the operation. With a few exceptions British surgeons have only turned their attention to the treatment of hypertension since the late war, and the 80 cases reported by Professor Platt and Dr. Stanbury [1] from Manchester a fortnight ago is the largest series so far published in this country.

There are three ways in which it is thought that sympathectomy may benefit hypertension. First, it dilates the blood-vessels in the splanchnic area (and, in some operations, in the legs) and so reduces the peripheral resistance. The importance of this factor in any given case can be judged by the fall in blood-pressure which occurs when the patient changes from the lying to the erect posture—that is, by the degree of postural hypotension. Secondly, sympathectomy denervates the kidneys, and in animals prevents the Trueta "shunt" mechanism from operating.[2] The evidence is far from conclusive, but the renal cortical ischæmia produced by this mechanism may be responsible for essential hypertension in man. Thirdly, sympathectomy denervates the suprarenal glands and prevents them forming adrenaline. This was formerly thought to be important, but it is doubtful whether adrenaline plays much part in hypertension except in the rare cases of tumours of the suprarenal medulla. Various types of operation have been performed. The one which Peet [3] introduced in 1933 consists in a supradiaphragmatic resection of both sympathetic chains from T 10 to T 12 and of the splanchnic nerves. Other surgeons have extended the operation to remove more of the thoracic chains, and Peet himself [4] often went as high as T 6 or T 5. The subdiaphragmatic operations of Craig and Adson [5] and of Crile [6] have now been largely abandoned. Smithwick introduced the operation which most surgeons are now doing. Being dissatisfied with the results of both supradiaphragmatic and subdiaphragmatic approaches he combined the two in his thoracolumbar sympathectomy,[7] in which the sympathetic chains from T 9 to L 2 or lower and the splanchnic nerves are resected. Various extensions of this procedure have been practised by Smithwick and others,[8] including A. M. Boyd [1] in England; and Grimson [9] has advocated a "total" bilateral sympathectomy in which both sympathetic chains are removed from the stellate ganglion to L 3. Owing to the increased morbidity and mortality which accompany them, the more extensive procedures are not justified except in special circumstances, and Smithwick's original operation is now the standard procedure.

Peet and Isberg [10] and Smithwick [11] have published their results in large series of cases which have been very fully investigated and followed over at least five years. In Smithwick's 256 cases with continued hypertension the mortality was 2·2% per operation, and 31% were dead nine years later. The diastolic blood-pressure fell at first in 84% of cases, and in 35% it fell to below 90 mm. Hg. In those who survived from five to nine years, however, the corresponding figures were 47% and 21%. Sympathectomy apparently slows the progress of the cardiovascular disease, especially in those cases which show the greatest fall in blood-pressure. Actual improvement is often seen in the retinæ, in the heart-size and electrocardiograms, and in renal function. In spite of the late deterioration in blood-pressure, Smithwick claims that the survival-rate of the patients operated on, compared with that of hypertensives treated medically, is improved to a degree which is statistically highly significant in all except the mildest cases. The effect of the sympathectomy on symptoms is variable. Many of the patients are capable of more work than they were before operation. Headache is nearly always relieved even when the blood-pressure is not lowered. Platt and Stanbury [1] agree with Fishberg [12] that this is probably the result of a compensatory increase in vasomotor tone in the upper part of the body, which protects the capillaries in the head from the increased blood-pressure. The same mechanism often produces Raynaud's phenomena in the hands after thoracolumbar sympathectomy. Other symptoms are relieved less constantly, and some, especially angina pectoris and dyspnœa, may be increased. Chest complications and intercostal neuralgia are occasionally serious after the operation, and cerebral thrombosis may be precipitated by it.

The selection of patients for operation is not easy. Few would deny that a man or woman aged 40 to 50 with established hypertension, severe headaches, and other symptoms, a good myocardium, no permanent central nervous changes, and good renal function, should be given the benefit of sympathectomy. The more advanced cases, where the patients have had one or more strokes, are having anginal pain, and show retinal hæmorrhages and exudates and a renal function which is beginning to fail, are less promising material for surgery. Some of these die at operation or within a few months, but many do unexpectedly well and are completely relieved from their headaches. The surgeon needs more courage to operate on young patients with mild symptoms and a blood-pressure which fluctuates and is sometimes within normal limits. Platt and Stanbury consider that sympathectomy is too serious an operation to be justified in these patients, and they contend that there is no evidence that it prolongs their lives. De Takats et al.,[13] on the other hand, believe that there is a clear-cut indication for operation in this group, and that only in such patients is there a hope of cure. Patients with malignant hypertension should probably be operated on unless they are dying, because some will be saved, and without operation the prognosis is

very near to the iron atom of one or more of the hæms. so that when the iron is combined with oxygen or carbon monoxide the "complementariness" of the region is much diminished. When the oxygen tension is low the complementary regions can react with one another; this results in a new alignment of the molecules in the cell so that they become relatively rigid and the cell membrane becomes distorted to accommodate them: hence the sickling. The distortion would be a quantitative affair depending on the number of sites released by lowering the oxygen tension, and on the proportion of abnormal hæmoglobin present; this view fits in with the observed facts. The genetics of sickle-cell disease will also fit in with these observations. Neel[4] suggests that the gene responsible for sickling is heterozygous in persons with the sickle-cell trait, and homozygous in people with sickle-cell anæmia. This would fit the finding that people may have 100% normal hæmoglobin, 100% sickle-cell hæmoglobin, or 40% sickle-cell and 60% normal hæmoglobin; there are several possible explanations for the ratio in the mixed cases being 40 : 60 rather than 50 : 50. There does in fact seem little doubt that this is "a clear case of a change produced in a protein molecule by an allelic change in a single gene involved in synthesis."

The implications of this work are considerable. It may be that sickle-cell disease is a unique example of a disease due to abnormal hæmoglobin. But the fact is that here is an abnormal hæmoglobin which leads to a great shortening of the life of the containing red-cells, and so to anæmia in the patient with all the accompanying signs of in-vivo hæmolysis. There are other anæmias of this type that have not been satisfactorily explained, and in which the search for hæmolysins, in spite of some enthusiastic reports, has become more and more like a wild-goose chase. Pauling and his team propose to examine the hæmoglobin of other hereditary hæmolytic anæmias. Their results will not, we hope, be confined to hereditary cases only; there are equally anomalous and inadequately explained anæmias of this type which, on the surface at least, are not inherited; and the methods of investigation needed are quite beyond the resources of the purely medical departments.

PSYCHIATRY AND SKIN DISEASE

THE discussion on April 11 by the psychiatric section of the Royal Society of Medicine was concerned with the relation of psychiatry to dermatology, but many of the issues raised are applicable to a wider field of clinical medicine. Dr. R. M. B. MacKenna based his opening remarks on the classification of neurodermatoses adopted by Becker and Obermayer[5] and pointed out that the types of cutaneous reaction which have been attributed to emotional disturbance range from rosacea, which is characterised by chronic vasodilatation in a limited area, to alopecia areata, in which the skin is soft and white with no palpable change except loss of hair; and from pompholyx, which is characterised by considerable vesiculation with minimal vasodilatation, to various forms of lichen characterised by papule formation. He suggested that these highly selective mechanisms of response, which may be due to mental stress, require the elucidation not only of psychiatrists and dermatologists but also of physiologists, biochemists, and endocrinologists; for, though the cause of these maladies may be psychological, their appearance must be due to physiological and chemical changes in the skin. Until this basic scientific work is done the views of psychiatrists must largely be speculative. A second major issue which Dr. MacKenna raised was that once certain skin eruptions have been produced by psychological causes the symptoms can be perpetuated by mechanisms of infection, auto-sensitisation, and superimposed contact dermatoses which the patient's mind cannot control: and if these are not dealt with at the same time as the primary psychological cause the patient's condition is unlikely to improve. Here there is a particular need for team-work, since often the skeletons found in the patient's mental cupboard are not the sole cause of the perpetuation of his cutaneous symptoms. Dr. MacKenna's views were largely supported by Dr. W. J. O'Donovan, and Dr. H. J. Wallace made a plea for the use of controls in psychiatric investigations. That, in brief, was the case for the dermatologists, and analogous views could no doubt be advanced in regard to most branches of medicine.

For the psychiatrists, Dr. E. Wittkower, who has studied the psychosomatic aspects of dermatology in the Army and at St. Bartholomew's Hospital, classified skin diseases associated with emotional conflicts in two groups, according to whether skin sensations are paramount (e.g., pruritus ani and pruritus vulvæ) or skin manifestations are predominant (e.g., rosacea and some forms of endogenous eczema). Dr. E. B. Strauss emphasised the importance, in dealing with all psychosomatic problems, of distinguishing between the terms "psychic" and "psychogenic." Teleologically, psychic processes do not necessarily involve a logical chain of cause and effect. Psychogenesis, on the other hand, presupposes such a purposive element, which is usually unconscious, and assumes that the processes can be consciously appreciated and modified by the use of psycho-analytical techniques. He suggested that there is a factor interposed between psyche and soma—this may be the "schema" as elaborated by Russell Brain in *Perspectives in Neuropsychiatry*—and that many psychodermatological problems might perhaps be formulated and solved in conceptual terms of that nature. Dr. H. J. Shorvon claimed that abreactive techniques will benefit several pruritic and some other eruptions which are unlikely to respond to routine dermatological treatment.

The discussion illustrated clearly the division existing today between psychiatrists and other clinicians. The clinicians, though sympathetic to many psychiatric views, would like more tangible evidence of the mechanisms whereby emotional agitation produces the physical disturbance which is visible—as in the skin—or demonstrable in other organs. Theories of ætiology based on the results of treatment have often proved fallacious in the past. It is not sufficient to say "I can cure this case by convulsion therapy, by abreaction with ether, by leucotomy, or by psycho-analysis," as the case may be, and "therefore its cause lies in the mind"; for similar ailments will often be cured, or at any rate relieved, by rest in bed and suitable applications. There is a cogent analogy in the work of William Withering[6] on the value of foxglove in dropsy. He recognised that digitalis had an action on the heart, but it remained for John Ferrier[6] to ascribe the diuresis of digitalis to a secondary effect of its primary action on the heart. The psychiatrists may well believe that in many cases such convincing evidence may be accumulated linking psychiatric cause with somatic effect that anyone who questions their conclusions is an iconoclast with whom argument is useless. And they are entitled to argue that since the clinician's job is to relieve human suffering they cannot wait for the slow elaboration of laboratory techniques to justify their beliefs. The psychiatrists may be congratulated on having achieved so much in the short time since the pioneers of modern psychiatry began their work. But the present babel of psychiatric opinion, and the recent for six to ten injections it has been reported[29] to relieve pain, and yet in large doses it apparently may initiate zoster.[30] For the moment the best hope seems to lie in aureomycin, though chloramphenicol[31] has also been favourably reported on.

Annotations

SICKNESS-RATES UNDER THE ACT

MANY foretold that the National Health Service would lead people to consult their doctors needlessly; and the greater demands made on medical services since the Act came into force are held by some to fulfil the prophecy. But it is hard to say how far the increased load is due to valetudinarianism or the desire to get something for nothing, and how far it comes from people who formerly could not afford to seek help as often as they should. Nor has it ever been made clear how great the increase has been.

In our present issue Dr. W. P. D. Logan gives figures derived from the continuous survey of sickness carried out for the Registrar-General. In this survey some 4000 people over the age of 16, living in various parts of England and Wales, were asked about their health for the two months preceding the inquiry—a period which is short enough to make recall easy. Dr. Logan compares the results in the first year of the health service—from July, 1948, to June, 1949—with those of the previous year, July, 1947 to June, 1948. In 1948–49, the number of people over 16 who complained of illness (the sickness-rate) was 5% higher, and the number of illnesses 8% higher, than in 1947–48. The number of days spent away from work or confined to the house (the incapacity-rate) rose by 22%, mainly owing to a great increase among women. The incapacity-rates for men went up by 8–9%, but women in the younger age-groups showed an increase of 32% more days of incapacity, and older women an increase of 41%—which, Dr. Logan says, are increases "far beyond what would be expected from the increase in illness that they suffered."

The average increase in medical consultation rates was 13%. The records show that women complain of illness much more often than men; and, since they are now in a position to consult their doctors more freely than they did, many of them are no doubt advised to stay at home for disorders which they would formerly have neglected. In other words the higher sickness-rates and absenteeism among women during 1948–49 may give a more accurate idea of the state of their health than the lower rates of the preceding year. It is interesting that while consultation-rates rose among men and women with incomes below £10 a week, they fell among those with incomes above that level.

As Dr. Logan points out, there are dangers in comparing rates over two years only: such things as an influenza epidemic or a hard winter can weight the scales unduly. If the rates for 1948–49 are compared, not with those of the preceding year, but with those of 1946–47, there are increases, certainly, but they are much smaller: the sickness-rate is higher by only 2%, the incapacity-rate by 5%, and the medical consultation rate by 8%. Time will show how much epidemics and infections can influence the picture: in 1946–47 there was a moderate amount of influenza but a very hard winter; in 1947–48 there was a mild winter and very little influenza; and in 1948–49 there was a moderate winter and a considerable influenza epidemic. The rates for 1947–48 may therefore be somewhat below the usual average, and those for 1948–49 higher. At all events the use made of the National Health Service by no means resembles a run on the bank, and can probably be largely explained by epidemic fluctuations and by the fact that some who formerly lacked necessary care are now getting it.

ABNORMAL HÆMOGLOBINS IN ANÆMIA

THE idea that the hæmoglobin in human red cells may not always be the same has been put forward from time to time. Jonxis,[1] for instance, showed that there are physicochemical differences between fœtal and adult hæmoglobins. But the possibility that the properties of an abnormal hæmoglobin might be primarily responsible for a blood disease had not been seriously considered. Now, however, Pauling and colleagues[2] have convincingly shown that sickle-cell disease is primarily due to the presence of an abnormal hæmoglobin and that this abnormality will explain the curious features of the disease.

In sickle-cell disease the red cells change their shape when exposed to a low partial pressure of oxygen; the normal biconcave disc becomes crescent-shaped or otherwise irregular, and these distorted cells are unusually fragile and are soon broken up. Sickle-cell disease exists in two forms: the sickle-cell trait and sickle-cell anæmia. People with the trait normally have about 1% of sickle-cells in the red cells of their venous blood: whereas in sickle-cell anæmia, on the other hand, 30–60% of the red-cells are sickled, even with no oxygen deprivation; and about 1 in 40 of people with the sickle-cell trait have the anæmia. It should be noted that at sufficiently low oxygen pressures *all* the red cells, whether from a person with the anæmia or with only the trait, can be made to sickle. Pauling and colleagues noted that in sickle-cell erythrocytes the hæmoglobin appears to be physically normal when combined with oxygen or carbon monoxide. But when the oxygen or carbon monoxide is removed, and the cell becomes sickled, the hæmoglobin seems to gather itself into one or more foci in the cell and the cell membrane collapses; the cell then becomes birefringent and rigid. Apparently these changes depend on the state of the hæmoglobin inside the cell and probably not at all on changes in the cell membrane. The next step therefore was to examine this hæmoglobin in detail by physicochemical methods such as electrophoretic mobility. The results, stripped of detail, show clearly that the hæmoglobin in the sickle-cell erythrocytes is abnormal. In sickle-cell anæmia the cells contain only sickle-cell hæmoglobin; in sickle-cell trait some elaborate measurements showed that each red cell contains a mixture of about 40% of sickle-cell hæmoglobin and 60% of normal hæmoglobin. The results so far also suggest that the proportion of sickle-cell hæmoglobin in the red cells of a person with sickle-cell trait is fairly constant.

What is the reason for the difference between these two hæmoglobins? Enough work on this point has already been done to show that the difference is in the globins; the hæm part of the molecule appears to be identical in each form. Within the limits of experimental error, say Pauling and his co-workers, "sickle-cell anæmia hæmoglobin has 2–4 more net charges per molecule than normal hæmoglobin." For the actual sickling process they propose the following hypothesis. They suppose that there is a surface region on the globin of the sickle-cell hæmoglobin molecule which is absent in the normal molecule and which is complementary to a different region on the surface of the hæmoglobin molecule. Such a situation probably exists in the antigen-antibody reactions.[3] This complementary region must be situated

ILLNESS, INCAPACITY, AND MEDICAL ATTENTION AMONG ADULTS, 1947–49

W. P. D. LOGAN
M.D., B.Sc. Glasg., D.P.H.
MEDICAL STATISTICIAN, GENERAL REGISTER OFFICE

THE number of times that people are ill, the length their illnesses, and how often they consult their doctor e matters of some concern to the medical profession. ie purpose here is to compare the prevalence of illness nong adults, the duration of incapacity, and the equency of consultations between patients and doctors uring the twelve months from July, 1948, to June, 1949, id the previous twelve months from July, 1947, to une, 1948.

The information has been obtained from the conuous Survey of Sickness carried out on behalf of the egistrar-General. Each month trained interviewers the Government Social Survey visit a different sample some 4000 persons, aged 16 and over, living in various arts of England and Wales, the samples being so lected as to represent the whole adult population. he selected individuals are asked about their health uring the two previous months, the illnesses and injuries ey suffered, how long they were kept off work or revented from going out of doors, and how often they onsulted a doctor. After tabulation at the General Register Office the results of the interviews are published in the Registrar-General's Quarterly Returns.[1] The return for the first quarter of 1949 (no. 401) included a note on the prevalence of sickness, incapacity, and medical consultations during July–December, 1948, compared with corresponding months in the two previous years. Descriptions of the methods used in the Survey of Sickness since it began in October, 1943, and of some of the results have been given by Stocks,[2] Box and Thomas,[3] and Slater,[4] in Ministry of Health reports,[5] and in the *Monthly Bulletin of the Ministry of Health.*[6]

ABLE I—MEAN MONTHLY SICKNESS, PREVALENCE, INCAPACITY, AND MEDICAL CONSULTATION RATES PER 100 PERSONS INTERVIEWED: JULY–JUNE, 1947–48 AND 1948–49

	Male		Female		Persons
	16–64 years	65 years and over	16–64 years	65 years and over	16 years and over
ickness-rates:					
1947–48	58	76	68	85	66
1948–49	61	79	72	87	69
ercentage difference	+6	+4	+6	+3	+5
revalence-rates:					
1947–48	105	166	150	218	139
1948–49	115	175	164	230	151
ercentage difference	+9	+5	+9	+5	+8
ncapacity-rates:					
1947–48	89	148	72	159	90
1948–49	96	162	94	223	110
ercentage difference	+8	+9	+32	+41	+22
ledical consultation rates:					
1947–48	35	60	38	57	40
1948–49	37	65	45	69	45
Percentage difference	+6	+9	+18	+22	+13

The fullest report on results is that by Stocks,[7] who proposed definitions for morbidity statistics, studied the effect on recorded sickness of such factors as memory, sex, age, and season, and compared the prevalence of a few important diseases, as indicated independently by the survey and by special food allowance statistics (derived from form R.G. 50) and found these two sources to be in close agreement.

DEFINITIONS

Here the periods 1947–48 and 1948–49 are the twelve-month periods from July, 1947, to June, 1948, and from July, 1948, to June, 1949, the latter period being of course the first twelve months of the National Health Service. Tables II and IV, however, also include periods from July, 1946, onwards. The rates in the tables are mean monthly rates—that is, they refer to the average monthly experience of the periods stated. It must be emphasised that the records relate only to persons aged 16 years and over.

In general morbidity studies it is essential to distinguish between the number of persons ill and the number of illnesses reported, because patients are liable to suffer from more than one illness or injury in a month. Sickness-rates are defined as the number of persons per 100 interviewed who report at least one illness or injury during the month. It follows that each person can contribute no more than one unit to the sickness-rate for the month, and that the rate can never exceed 100. Prevalence-rates, on the other hand, are defined as the total number of illnesses and injuries reported per 100 persons interviewed, whether these occur simultaneously or consecutively during the month; and theoretically there is no limit to the number of illnesses that may be reported. Incapacity-rates are the number of days away from work on account of illness during the month per 100 persons interviewed; or, for persons not going out to work, the number of days on which they were prevented by illness from going out of doors. Medical consultation rates are the number of visits during the month made to, or by, a doctor (including medically qualified ophthalmic or other specialists, but excluding dentistry and attention whilst an inpatient in a hospital) per 100 persons interviewed.

RESULTS

In 1948–49 the number of people, aged 16 and over, who complained of illness (the sickness-rate) increased

TABLE II—MEAN MONTHLY SICKNESS, PREVALENCE, INCAPACITY, AND MEDICAL CONSULTATION RATES PER 100 PERSONS INTERVIEWED: JULY–JUNE 1946–47 AND 1948–49

	Male		Female		Persons

discovery that widely diverse techniques, which would seem likely to have very different effects on the brain, can cure or ameliorate somatic symptoms, tend to confuse their well-wishers and give ammunition to their opponents. We must be content to wait for those who are striving to establish a new branch of medicine to set their house in order, remembering that philosophical speculation without solid scientific foundations has often proved to be the path of error. There is a need for laboratory investigation and team-work with scientists and clinicians to be more widely incorporated in psychiatric work, and in the study of psychosomatic medicine dermatology seems to offer the most accessible avenue for research.

ERADICATION OF VENEREAL DISEASE ?

THAT endemic diseases can be speedily eliminated has been shown by the eradication of malaria from large areas and even (as in the case of Cyprus [1]) whole countries. An eradication attempt of a different sort—more ambitious because its aim is to remove the source of infection in man rather than eliminate an insect vector—is to be made in Haiti, where penicillin is to be applied to the extinction of venereal disease. In this island republic about 25% of the $3^1/_2$ million population are said to have venereal disease; and some 85% have yaws, which it is hoped to eradicate at the same time. Ten mobile units will tour the island giving injections of penicillin to all inhabitants. The campaign, which is being undertaken by the World Health Organisation along with the government of Haiti and the United National International Children's Emergency Fund, is expected to take two years to complete.

This bold undertaking will be watched with close attention ; for if the attempt succeeds here it may also succeed elsewhere. Much will depend on convincing populations that the effort is worth making.

REMUNERATION OF MEDICAL CIVIL SERVANTS

THE Chancellor of the Exchequer has rejected a claim for improved remuneration of medical civil servants, but proposes to set up a committee to investigate the question. The joint committee which submitted the claim decided at a meeting last Monday to seek a further interview with the Chancellor. It objected that the proposed committee was inappropriately constituted to consider medical salaries (perhaps because medical members would be in a minority) ; and it decided to ask the British Medical Association to reject advertisements of civil-service appointments.

In submitting its claim last summer, the committee (comprising representatives of the Institution of Professional Civil Servants, the British Medical Association, and the Ministry of Health Medical Staff Association) urged that remuneration in the civil service should be aligned with that in the National Health Service—a change that would involve raising salaries at the Ministry of Health by £2000 in the case of the chief medical officer, and by close on £2000 in certain other grades. The Treasury reply states that the Chancellor

> "fully recognises the need for maintaining the efficiency of medical establishments, and, indeed, of other important establishments which are at present below strength. But in his view it is even more important to maintain the policy of wages stabilisation and he thinks that the success of that policy would be gravely jeopardised if he attempted exceptions to the general rule. However satisfactory to the claimants concerned the arguments justifying an exception in their favour might be, a concession made at the present time would be bound to cause misunderstanding and resentment among the rest of the community who would regard it as preferential treatment. He is also unable to agree that settlement of a claim by Civil Service doctors can be considered except as a Civil Service claim to be dealt with on the basis of the policy applied to the Civil Service generally."

The Treasury's difficulty is clear ; but the justification for the committee's claim is equally clear, for even in 1939, as we have pointed out,[1] the remuneration of medical civil servants was out of harmony with the times. Furthermore, the joint committee can protest that in offering disproportionate rates in the National Health Service and in the various Departments, the Government is being neither fair nor wise ; and the result will be continued weakening where strength should be greatest. Nor can the committee be blamed if it views with some reserve the proposal to set up a fresh committee. Apart from the fact that the deferment of the Chorley Committee's recommendations does not encourage faith in prompt action through any further body, the Treasury is known itself to have been investigating the difficulties of recruiting medical men to Government Departments. What, then, can another committee offer except time to the Treasury ?

THE BUDGET

TEMPORARILY at least, the economic crisis has receded, and Sir Stafford Cripps on Tuesday found it unnecessary to make his new Budget greatly different from the last. There has been enough industrial recovery, he thinks, to prove that " we are not being crushed by taxation." On the other hand, any further increase of Government expenditure would be difficult : " we have taken on, by way of social services and benefits during the last four years all we can possibly afford until such time as there is a large increase in our national production. And even then I have no doubt that the individual will want to retain a very considerable portion of that increase for his own spending." The largest addition for the coming year is another £133 million for the National Health Service, and the Chancellor made it plain that no excuse would be accepted for exceeding the estimate : any expansion in one part of the service must in future be made by economies, or if necessary contraction, in others. In exercising this essential control in total health expenditure regard will be paid to priorities of service, and if the Health Departments have difficulty in carrying out such priorities an amending Act can be passed. The proposal to charge patients 1*s.* on each prescription is to be held in reserve, for it is hoped that administrative methods of economising in this branch more easily can shortly be introduced. Food subsidies are to be held at their present level, but the rate of house-building is to go back to what it was before last autumn's cuts. The first £50 of taxable income is to be taxed at 2*s.* 6*d.* instead of 3*s.*, and the next £200 at 5*s.* instead of 6*s.* ; but, what the Notes on Allowances cheerlessly call " the balance, if any," will still attract tax at 9*s.* in the £, or more. Doctors will have less reason than most to rejoice that the standard ration of petrol is to be doubled—and more reason than most to regret that the price is to be raised by 9*d.* a gallon. What the Chancellor is proposing, as he said, is " the increase of an indirect tax which is very broadly spread in order to give proportionately more relief in direct taxation to the lower-income groups, although all income-tax payers will get some benefit."

DR. F. M. BURNET, F.R.S., professor of experimental medicine in the University of Melbourne, will give a lecture at the London School of Hygiene, Keppel Street, W.C.1, on Tuesday, May 9, at 5.30 P.M. He is to speak on the General Pathology of Virus Infection.

THE council of the British Medical Association decided on April 5 to establish a committee for the purpose of reviewing general practice after the first two years of the National Health Service. The council also agreed to publish the report of the committee which was set up, under the chairmanship of Sir Henry Cohen, to consider the postgraduate education of general practitioners.

[1] *Lancet*, Jan. 14, p. 81.

[1] *Leading article*, *Lancet*, Jan. 14, p. 75.

1946–47, practically none in 1947–48, and quite a severe epidemic in 1948–49 between February and April, 1949. This epidemic was responsible for some of the increased incidence of sickness, incapacity, and medical consultations during the last period.

Table III gives rates for the two twelve-month periods 1947–48 and 1948–49 with greater detail of age. A noteworthy feature about these rates is the tendency for practically all of them to increase uniformly with advancing age. Probably the only real exception is in the incapacity indices among women where the rate at ages 16–24 was higher than at ages 25–34. The reason presumably is that there are many more housewives in the older age-group, and housewives are a class of women who are less readily incapacitated for their work by illness than younger women in other occupations.

Table IV gives monthly rates for all adults by separate quarters from July, 1946. More detailed rates by sex, age, and single months have been given in the Registrar-General's Quarterly Returns nos. 401 (with special note), 402, and 403 (table A). The highest sickness, prevalence, and medical consultation rates, and the *second* highest incapacity-rate for any quarter were recorded in January to March, 1949, during the influenza epidemic.

Tables V and VI show the proportions of people who had different numbers of days of incapacity and medical consultations per month. In each sex-age group the proportion with no days of incapacity and the proportion with no medical consultations decreased, the reduction being greater among women than men, and greater among the elderly than among younger adults. The greatest relative increases in days of incapacity were among the proportions who had 4–10 days and 11 or more days of incapacity. For medical consultations the proportions having 1, 2, and 3 or more consultations all increased, but the increase was greatest among those women aged 16–64 who saw their doctor once in the month.

TABLE VII—PERCENTAGE DISTRIBUTION OF ILLNESSES BY CATEGORY OF SEVERITY (SEXES COMBINED): JULY–JUNE, 1947–48 AND 1948–49

—	Serious	Moderate or mild	Minor	Ill-defined.	Total
Aged 16–64 years:					
1947–48	2 2	5 4	70 8	21 6	100
1948–49	2 3	6 0	65 1	26 6	100
Aged 65 and over:					
1947–48	12 1	4 5	67 6	15·8	100
1948–49	11 4	5 2	63 3	20 1	100

The number of illnesses reported by all adults increased by 8% (table I). It may be asked whether this was an increase in illness of all grades of severity, or whether it consisted predominantly of minor and relatively trivial conditions. Table VII supplies the answer, showing that though there was an increase in "ill-defined" illness this was at the expense of "minor" illness. Thus there was no great redistribution in the severity of reported illness, and there is nothing to suggest that the increase has been due to illness of a trivial nature.

Tables VIII and IX analyse the results by occupation and by income; but to avoid having very small numbers [illegible] different classes, only very wide occupational [illegible]come groupings have been made. Table VIII [illegible] rates for four large occupational groups [illegible]ishing men from women): (*a*) professional, [illegible]al, and clerical occupations; (*b*) operatives [illegible] grades, including persons engaged in manu[illegible] transport and public services, mining and [illegible] building, agriculture and fishing, distribu[illegible]ther specified employment; (*c*) retired, part-time, and unoccupied persons and those whose occupation was not stated; and (*d*) housewives. To some extent the experiences of the different occupational groups depend upon their age structure, but it has not been possible to make any adjustment for this. The high rates in the group of retired and other persons arise from this cause. Housewives, it will be observed, had high sickness, prevalence, and medical consultation rates compared with women in other occupations. Their incapacity-rate in 1947–48 was not proportionately high, but it underwent an increase of 40% in the next twelve months. By contrast, there was a reduction of 1% in incapacity among men in the group of miscellaneous trades. Medical consultations for women in professional, managerial, and clerical occupations diminished by 3%, while those for women in miscellaneous employment increased by 23% and for housewives by 20%.

TABLE VIII—MEAN MONTHLY SICKNESS, PREVALENCE, INCAPACITY, AND MEDICAL CONSULTATION RATES PER 100 PERSONS AGED 16 YEARS AND OVER, BY OCCUPATIONAL GROUPS: JULY–JUNE, 1947–48 AND 1948–49

—	Professional, managerial, and clerical		Operatives and other grades		Retired, part-time, unoccupied or unstated		Housewives

by 5%, and the number of illnesses increased by 8%, compared with 1947–48 (table I). The increases were greater among those aged under 65 than among older people. The number of days away from work or confined to the house (the incapacity-rate) increased by 22%, but there was a great difference between men and women. Younger men showed an increase of 8% and older men of 9%. Younger women, on the other hand, reported 32% more days of incapacity and older women 41% more—increases that are far beyond what would be expected from the additional illness that they suffered.

Medical consultation rates increased by 13%. This is a measure of the average increase, over the whole country, in the number of consultations between *adult* patients and doctors during 1948–49, compared with 1947–48. In many practices the increase was no doubt well above this average figure, but in others it would be much less, depending largely, as will be seen, upon the proportion of women patients in the practice, and their age and general income level. The average increases for men were 6% for those under 65, and 9% for those aged 65 and over. For women the increases were much greater—18% among the younger and 22% among the older women. There can be little doubt that before the start of the new National Health Service many women—especially, but not exclusively, elderly women—were deterred from seeking medical advice by economic reasons. Now that the financial barrier has been removed, women, who, as the records show, complain of illness considerably more often than men, are able to consult their doctor more often than they did before.

TABLE III—MEAN MONTHLY SICKNESS, PREVALENCE, INCAPACITY, AND MEDICAL CONSULTATION RATES PER 100 PERSONS INTERVIEWED, BY SEX AND AGE: JULY–JUNE 1947–48 AND 1948–49

TABLE V—PERCENTAGE DISTRIBUTION OF PERSONS INTERVIEWED BY DAYS OF INCAPACITY PER MONTH: JULY–JUNE, 1947–48, AND 1948–49

—	No. of days of incapacity									
	Male					Female				
	0	1–3	4–10	11 +	Total	0	1–3	4–10	11 +	Total
Aged 16–64 years:										
1947–48	92·0	2·5	2·5	3·0	100	92·6	2·6	2·5	2·3	100
1948–49	91·2	2·8	2·7	3·3	100	90·7	2·9	3·2	3·2	100
Aged 65 years and over:										
1947–48	90·1	1·8	3·1	5·0	100	90·1	1·4	3·1	5·4	100
1948–49	88·7	2·1	3·7	5·5	100	86·8	1·7	3·5	8·0	100

It seems likely that the increased number of days of incapacity reported by women has been a direct consequence of more frequent medical attention. Since July, 1948, some of the women who have seen their doctor about complaints that they would previously have neglected or treated themselves have been ordered to bed or advised to stay indoors until they recovered. Among men, both young and old, the increase in incapacity and in medical consultations was no more than would result from their slightly increased rates of illness.

There are certain dangers in comparing the experience of one twelve-month period with only the previous twelve months, and it would be more satisfactory to make comparisons with similar periods over a number of previous years. Unfortunately the tabulations of the Survey of Sickness, in their present form, go back only as far as July, 1946 (and have been published only since October, 1946), so that no more than one additional twelve-month period can be studied—from July, 1946, to June, 1947. Table II compares rates for this period with those for 1948–49; and from this table, in conjunction with table I, it can be seen that the increases in 1948–49 compared with 1946–47 were smaller than those for 1948–49 compared with 1947–48, especially with regard to incapacity. It will be recalled, however, that the winter of 1946–47 included a protracted period of exceptionally weather—the coldest in fifty years or more—and that time sickness, consultation and, most incapacity rates were very high. The period Jul to June, 1947, fails, therefore, to provide an al satisfactory gauge against which to set su experience.

TABLE VI—PERCENTAGE DISTRIBUTION OF PERSONS INTERVIEWED BY NUMBER OF MEDICAL CONSULTATIONS PER MONTH: JULY–JUNE, 1947–48, AND 1948–49

In addition to weather, a further factor to the presence or absence of epidemic influen was a moderate amount of influenza in th

New members: C. E. Clarke; The Rev. Arthur Perry; J. E. Roberts; Councillor F. Mansell (until March 31, 1952); one appointment outstanding.

MANCHESTER REGION

Reappointed: Sir **John Stopford,** F.R.S. (chairman); Alderman G. D. Hastwell; William Onions, J.P.; Prof. **H. S. Raper,** C.B.E., F.R.C.P., F.R.S.; C. M. Skinner, F.C.A.; **J. D. Silverston,** M.B.; J. T. Waite; Mrs. Edith Watson, J.P.

New members: Mrs. Marjorie Bayes; W. Barnes.

LIVERPOOL REGION

Reappointed: Thomas Keeling, J.P. (chairman); Miss A. L. Bulley; Sir **Henry Cohen,** F.R.C.P.; H. O. Ellis, J.P.; **A. A. Gemmell,** F.R.C.O.G.; T. W. Harley, M.B.E., M.C.; **J. E. Nicole,** O.B.E., L.M.S.S.A.

New member: Alderman Hugh Platt.

The Secretary of State for Scotland has made the following appointments to the five Scottish boards. Out of 40 appointments, 27 are reappointments of retiring members. Those now appointed will hold office until March 31, 1953.

NORTHERN REGION

Reappointed Miss M. B. Clyne, S.R.N., C.M.B.; J. A. Farley; **I. H. Maciver,** M.B., J.P.; the Rev. Father Neil MacKellaig.

New members: J. A. McDonald, J.P.; J. Munro; Norman Robertson (until March 31, 1951).

NORTH-EASTERN REGION

Reappointed: **A. Greig Anderson,** F.R.C.P.; Provost **W. J. Lyon Dean,** M.B.; James Hay; Miss Bell Jobson; Bailie H. J. Milne, M.C. Robert Ollason.

New members: Mrs. J. Wolrige-Gordon; **A. C. Macdonald,** M.C., M.B. (until March 31, 1952).

EASTERN REGION

Reappointed: **W. L. Burgess,** C.B.E., F.R.C.P.E.; Councillor J. R. Christie; **James Lawson,** M.D.; Mrs. A. L. Matthew; Councillor **J. D. Saggar,** M.B.

New members: Miss M. C. Cameron, S.R.N.; **W. D. Chambers,** F.R.C.P.E.; J. J. Duffy (until March 31, 1952).

SOUTH-EASTERN REGION

Reappointed: James Black, J.P.; Mrs. I. McNeill; Prof. W. Oliver, B.SC., A.M.I.C.E.; **Andrew Simpson,** M.B.; Sir **Henry Wade,** C.M.G., D.S.O., F.R.C.S.E

New members: **William Boyd,** M.B.; Councillor Mrs. Jane Dowie; Councillor W. M. Inglis; Bailie D. R. Matheson, LL.B.

WESTERN REGION

Reappointed: **J. Bruce Dewar,** F.R.C.O.G., J.P.; J. Finlay; S. McLaren; the Hon. Mrs. Maclean of Ardgour; **Angus McNiven,** F.R.C.P.E.; Councillor J. Stewart, J.P.; **J. H. Wright,** M.D.

New members: **T. Anderson,** M.D.; Prof. I. W. Macdonald, C.A.; Mrs. C. M. Matheson; Bailie W. Muir; J. Forde, J.P. (until March 31, 1951); J. Aitchison, L.D.S., Councillor F. Gormill, and **Benjamin Hutchison,** M.C., M.B., J.P. (all until March 31, 1952).

Parliament

Medical Officers in the Forces

IN the course of a debate on defence in the House of Lords on April 5 Lord WEBB-JOHNSON said that in 1948, in pointing out the shortage and lack of quality of medical officers in the Forces, particularly in the Army, he had agreed that it was necessary to have a higher age for the call-up of medical and dental officers than for other conscripts. But at the same time he had warned them that even by raising the age to 30 there might still be a shortage. He had then advised integration, particularly with the National Health Service. The position was now worse, and it would grow steadily worse during the next two years. In 1952 the shortage of medical officers for the Army alone would be about 500, because 800 of the men leaving medical schools in that year would have finished their military training; and there would be no improvement until 1954. The shortage of specialists, he continued, was really alarming. Our young men were being sent to distant garrisons, and responsible members of the medical profession were certainly not satisfied—nor was the Director-General of Army Medical Services—that there was an adequate supply of specialists to care for them. The R.A.M.C. could not from its regular officers undertake to provide the requisite number of specialists, who nowadays had to have long training and wide experience. In some of the specialties the Service could not provide any. A young general-duty officer in the R.A.M.C., who aspired to be a specialist in surgery, could not secure adequate experience in the Corps. At present the R.A.M.C. required 114 specialists for the half year. Of these, 24 were surgeons. But the number available to fill the requirement of 114 was only 12. The position was not a temporary one; there was going to be a permanent shortage. The regular R.A.M.C., even with its full establishment of regular officers, could not provide the specialists in peace-time; there would be a shortage of 280. With the short-term commissions granted for a period of years, and including a proportion of specialists, the shortage would still be 142; and with the call-up of young men with some experience in the specialties, the shortage again was 122. To bring in civilian specialists and give them higher pay than officers of the same rank, as had been done, was a frightful and frightening experience. It was unsatisfactory, it was unfair, it was expensive, and it did not provide a permanent solution. Some of the remedies suggested were palliative—for instance, an adequate supply of transport to enable a specialist to cover more cases, or that the Services should accept a lower physical standard for specialists, particularly those who were not serving under war conditions. But the fundamental point was dealt with in paragraph 23 of the statement on defence, which said: "A high level of recruitment cannot be expected unless Service conditions compete in attractiveness with those of civilian life."

The first requirement was that the pay of the regular officers should be advanced. Some regular officers serving now were anxious to retire. There was a ban on retirement. Would that policy lead to a contented Service? In fact there was considerable discontent. The regular and short-term establishments could be increased, but that was no solution. The only way to get a specialist service for the Army under the present National Service Act was by obtaining civilians. There was a suggestion that the civilian age for recruitment should be raised to 45 years. It would be a serious matter if the specialist section of the population should have legislation levelled against them that might interfere with their careers up to the age of 45.

Lord Webb-Johnson still thought the right solution was some integration with the National Health Service. Those who held whole-time posts in that service should be appointed with a definite obligation to accept from time to time secondment to the Forces, and they should be able to return to the civilian service without loss of seniority and promotion. The integration of the Forces' medical services with the National Health Service and with the Colonial medical services would do much to enhance the reputation of the Commonwealth and Empire. It was a matter of extreme urgency, and if the hold-up had been at the Treasury it was time that pressure was brought upon that Department to permit of a solution being obtained.

Lord HADEN-GUEST said that as chairman of the Medical Priority Committee, he agreed that the situation in respect of recruitment to the Service was grave as regards both general-duty officers and specialists. The fact that during the next two years so many men who would normally be called up for 18 months' duty would not be available, because they had exhausted their military service obligations before becoming qualified, was temporary. But it did not make the situation at the moment any less serious. In his view the final solution was to regard the National Health Service as the mother and father of all the medical services, including the Colonies and the Services. It should be regarded the under-£3 group, which contains a large proportion of elderly pensioners. In both sexes there is a general tendency for illness to decline as income rises. The increase in the sickness and prevalence rates in 1948–49 compared with 1947–48 was not concentrated at any particular income level, and there was little difference between men and women. More days of incapacity were reported at every income level but in the groups from £4 up to £10 the increase among women was much greater than among men. Medical consultations also increased unequally in the two sexes at incomes under £3 and from £4 to £10. The greatest increase in consultations was at £3–4—a 41% rise for men and for women. Standing out in very sharp contrast, men and women in the group with incomes of £10 and over saw their doctor *less* often after July, 1948, than in the previous twelve months, despite a slight increase in illness. That section of the population who could best afford to pay for medical attention under the old system appear to have taken least advantage of the new; whilst people with more limited incomes, especially women, who formerly saw their doctor less often than they should have done—or at any rate less often than those with more money—have found it possible since July, 1948, to have medical attention more in keeping with the amount of illness of which they complain.

SUMMARY

A study of the results of the Survey of Sickness for the twelve-month period July, 1948, to June, 1949, compared with the previous twelve months, has shown that 5% more adults aged 16 and over had some illness, and that the number of individual illnesses increased by 8%. The number of days of incapacity (days away from work or kept indoors on account of illness) increased by 22%, and the number of consultations with doctors increased by 13%.

The increase in incapacity and in medical consultations was greater among women than men and greater among elderly than young adults.

Persons whose chief wage-earner had a small income, especially women, formerly had less frequent medical attention than those who could better afford to pay for it. Since July, 1948, the number of medical consultations among those in the small-income groups has greatly increased, but among those with large incomes they have become less.

REGIONAL HOSPITAL BOARDS

THE Minister of Health has made the following appointments mainly to fill vacancies caused by the retirement of a third of the members of the 14 boards in England and Wales. Out of 131 appointments, 93 are reappointments of retiring members; 1 appointment is still outstanding. Those now appointed will hold office till March 31, 1953. The names of the medical profession are shown in bold type.

NEWCASTLE REGION

Reappointed: Sir Walter Thompson, J.P. (chairman); Miss D. R. Gibson, S.R.N.; Prof. **R. Bramble Green,** F.R.C.S.; Prof. **W. E. Hume,** C.M.G., F.R.C.P.; **J. R. Murray,** M.D.; Lord Eustace Percy, P.C.; Viscountess Ridley; T. C. Squance, O.B.E.

New members: John Lisle, J.P.; Mrs. A. E. Venables.

LEEDS REGION

Reappointed: Alderman David Beevers, J.P.; **G. W. Black,** F.R.C.S.; B. Hazell, M.B.E.; W. L. Lawton, C.B.E., J.P.; **J. Ivison Russell,** M.D.; F. Stuart.

New members: C. R. Morris; H. J. Edwards; Miss A. Whalley, M.B.E., S.R.N. (until March 31, 1952).

SHEFFIELD REGION

Reappointed: Sir Basil Gibson, J.P. (chairman); Miss **Margaret Bott,** F.R.C.O.G., J.P.; **K. K. Drury,** M.C., M.D.; A. R. Martin; Theophilus Pearson, J.P.; Prof. **G. L. Roberts,** M.B., B.D.S.; E. W. Scorer, O.B.E.

New members: **Hugh Barber,** F.R.C.P.; Alderman Mrs. F. L. Green, J.P.; Councillor J. E. Worrall; Alderman A. E. McVie, J.P.

EAST ANGLIAN REGION

Reappointed: Earl of Cranbrook (chairman); **M. W. B. Bulman,** F.R.C.S.; **R. B. Fawkes,** D.S.O., M.C., M.R.C.P.; James Grantham; Alderman Sam Peel, J.P.; E. W. Plumpton, J.P.; G. T. Vawser.

New members: Alderman H. S. Matthes; Alderman E. G. Gooch, C.B.E., M.P., J.P.; Prof. **A. L. Banks,** F.R.C.P. (until March 31, 1951).

NORTH-WEST METROPOLITAN REGION

Reappointed: Fred Messer, C.B.E., M.P., J.P. (chairman); Prof. **S. J. Cowell,** F.R.C.P.; **A. Stavely Gough,** F.R.C.S.; Henry Lesser, O.B.E.; Prof. **James Mackintosh,** F.R.C.P.; Miss M. Marriott, S.R.N.; Sir Owen Morshead, K.C.V.O., D.S.O., M.C., D.L.; Miss **Esther Rickards,** F.R.C.S.; Prof. **H. W. C. Vines,** M.D.

New members: **S. A. Mackeith,** M.R.C.S.; Mrs. M. E. Burns.

NORTH-EAST METROPOLITAN REGION

Reappointed: J. W. Bowen, C.B.E., J.P. (chairman); **Louis Comyns,** L.R.C.P.E.; Lieut.-Commander Horace Denton; Major R. P. Woodhouse.

New members: Prof. **Victor Dix,** F.R.C.S.; T. R. Haggarty, L.D.S.; Mrs. R. Rees-Thomas.

SOUTH-EAST METROPOLITAN REGION

Reappointed: K. I. Julian, C.B.E. (chairman); **E. R. Boland,** C.B.E., F.R.C.P.; Lord Cunliffe; *The Very Rev.* T. Crick, C.B.E., M.V.O.; **A. Talbot Rogers,** M.R.C.S.; E. C. Sherwood.

New members: C. F. Bowes; R. J. Mellish, M.P.

SOUTH-WEST METROPOLITAN REGION

Reappointed: F. H. Elliott, D.L., J.P. (chairman); Mrs. Helga Feiling; **C. B. S. Fuller,** M.C., M.R.C.P.; Miss P. Loe, M.B.E., S.R.N.; **M. F. Nicholls,** C.B.E., F.R.C.S.

New members: Miss M. O'Conor; **Louis Minski,** F.R.C.P. S. R. Thorogood; Mrs. E. Hailstone.

OXFORD REGION

Reappointed: **A. R. Banham,** F.R.C.S.; Prof. **T. Pomfret Kilner,** C.B.E., F.R.C.S.; Colonel C. B. Krabbé, O.B.E., D.L.; *Miss Rosemary Spooner;* ***J. A. Stallworthy,*** F.R.C.O.G.

New members: Captain F. Gardiner, M.C., J.P.; J. R. Cole; J. W. W.-Cripps; Mrs. Lilian Davies (until March 31, 1952).

Chairman: Dr. **Janet Vaughan,** F.R.C.P., has been appointed chairman until her term of membership expires on March 31, 1951.

SOUTH-WESTERN REGION

Reappointed: H. G. Tanner, J.P. (chairman); Sir Philip Morris, C.B.E.; **C. T. Andrews,** F.R.C.P.; Colonel H. Bland Stokes, M.B.E.; Mrs. K. A. Goddard, J.P.; P. E. Russell; Brigadier J. Morrison, M.B.E.

New members: Alderman V. J. Ross; H. M. Medland; Mrs. M. Ball.

WELSH REGION

Reappointed: Sir Frederick Alban, C.B.E., J.P. (chairman); Alderman William Casey, J.P.; T. P. Davies; Alderman W. C. Davies; Alderman Joseph Dicks; Alderman J. J. Panes, O.B.E.; Alderman **D. H. Pennant,** D.S.O., M.D.; Prof. **O. H. Williams,** F.R.C.S.

New members: Sir Ivor Thomas, J.P., D.L.; Eddie Jones.

BIRMINGHAM REGION

Reappointed: R. R. Adam (chairman); **J. A. Brown,** M.D.; Alderman W. Hutson, J.P.; Alderman J. Latham, J.P.; Alderman Leonard Whitehouse, J.P.; Alderman Percy Williams, J.P.

In England Now

A Running Commentary by Peripatetic Correspondents

SPRING is the proper time for picture shows, for then the eye and mind are eager for refreshment, and respond sympathetically to the other fellow's vision. The Medical Art Society now exhibiting at Walker's Galleries, are good company this year, whether you follow A. C. Dalzell to Africa or Sir Philip Manson-Bahr to Suva, loiter round Newlyn with C. Branwell, or even stay at home and cook kippers with Dorothy Hare. Dalzell's "African Landscape" is big and sinister, with grey banyan roots writhing down into water (does African water not refract?), while beyond them the soft quality of palm trees contrasts with the hard sturdy green of their colour. Never a gleam on land or sea for Dalzell; his "Jungle Cock," gloriously confident in the thick tropical forest, has no sheen on his feathers, and the leaves about him are as mat as felt. This strange practice gives his pictures a sorrowful exactness, shared by A. B. Hewlett's "Tree" and "Boathouse." The tree—a neatly riven willow—grows beside a new brick byre of a pleasant pinkish colour; I liked it better than the boathouse, which somehow failed to evoke the smell of varnish, the trembling light, and the interminable clink of water proper to such places. Sir Philip's banana trees, lying beside the light-filled bay, are delicately lively; and this is the more to his credit since he was using water-colours while the others used oils. Another water-colour of great charm was "Bartholomew the Less," by Keith Vartan, in which the sunshine cuts slantwise across the tower, so dividing the colours that the buildings below make a warm foundation to the tower, floating in light.

Many of the water-colour landscapes showed a high level of technical competence without stirring my blood; but perhaps it runs sluggish these days, even in spring. I did notice with pleasure "Anemones" by Emanuel Miller, because the flowers—which were just going off, as he very honestly and skilfully showed—were so pleasantly grouped with a little glass-and-gilt dish and a matchbox. There were of course one or two deliberate shockers: "Sussex Fantasy," by R. H. Dale, showed a cartoonist's view of an operating-theatre; and S. D. Cudjoe depicted "Hallucinations of an Engine-Room Boy" as a turbaned figure rising from whorls of coloured cushions (perhaps), minutely rounded out in lines of coloured ink—a sort of doodle in excelsis.

But the French doctors, members of the Salon des Medicins, struck the authentic note of spring. They had contributed a whole wall of spirited paintings, and took their inspiration from the impressionists, the primitives, or the surrealists, according to temperament, or possibly mood. Pierre Masquin's harbour at La Ciotat, full of sunny blues, with a rust-red boat pulled up in dry dock, was balanced by Lucien de Gennes's more sober water-colour of St. Tropez harbour. Then there was a plate of shining mackerel and some agreeable pink fish lying beside a lemon and a jar of pink and yellow flowers, by François de Hérain, which I found unreasonably refreshing. How much gayer are these fish of France than Dorothy Hare's kippers, though she had done her best with the lively iris which gleams about the gills. Malespine had done two "compositions" which would make a suitable background for a ballet of the "Inferno": they were full of melting shapes, strange colours, and shafts of light, and invited interpretation as insidiously as a Rorschach test.

All this, and more, you may see for yourselves between 10 A.M. and 5 P.M. on weekdays and 10 A.M. and 1 P.M. on Saturdays till April 29.

* * *

☞ Now that the first holiday spasm is relaxing I find myself having to order in some bismuth again. My grateful N.H.S. patients will keep sending me highly coloured postcards from distant parts of the earth to enable me to share their joys. A very nice time they must be having, tossing their liras, francs, escudos, pfennigs, and other inaudible currencies from hand to hand, and no doubt hoisting a well-laden fork from plate to mouth. With Bibendum ogling beside them, disdaining a mere *pot de vin*, they shamelessly tuck a gleaming napkin into corsage or collar and battle on regardless. But not quite regardless. The postprandial twinges of Gaster remind them of me. They lick a stamp, perhaps moisten it with wine, scrawl a languid line, and a few days later my injured pylorus registers frustration. I reflect that they have spent as much money on the trip as I get in a quarter from them and their flock. But, bless them all! If it sets them up for the next few months, should I worry and will they worry me? The cynical reader will remark that they are certain to be back for some more phenobarbitone to help them face the rigours here. I merely reach for my beaker of bismuth and pick up the next card. "We are setting off on our Easter Mediterranean Cruise. As you see from the photo, the ship is pretty comfortable. . . ." Anyway, I shall be able to confirm or refute the above-mentioned cynic soon. I can't afford to go away for a holiday at all.

* * *

The *Journal of the American Medical Association* for March 11 has an editorial note (p. 732) on the disposal of unwanted medical samples, based on a suggestion received by the U.S. Post Office Department:

> May I suggest a notice to all professional men, especially of the medical group, not to throw unwanted samples, especially liquid mediums and laxatives, in lobby waste baskets? Many times youngsters delve through these baskets to find pictures or old stamps, and might sample the medicine with fatal results.

The same can no doubt be said of the British youngster, and even the dustbin is not a completely safe disposal place; I still come out in a cold sweat at the memory of my friend Jones's little boys, then aged 4 and 3 years, toddling cheerfully across the High Street of their home village, each grasping in one hand a sample bottle of shining silvery tablets and in the other a cobwebbed bottle obviously containing a stale sample of urine. And how they yelled when their just spoils from the surgery dustbin were taken from them!

Then there is the parallel problem of the patient who swallows a sample of some nostrum or other which distorts the clinical picture. When I was a resident, many years ago, I admitted a stalwart policeman for gastric investigation, and that evening the night nurse told me with some alarm that the patient's urine was bright blue. When I asked him what he had been taking he swore vehemently that he had had nothing unusual. I was then young enough to believe at least most of what a patient told me. I spent quite a while on that urine, but in view of his denial I did not get very far. I ordered a strict watch to be kept on the patient and next morning his urine was green. In the afternoon it was blue again. By this time it was dawning on me that I had not been told the whole truth; so sending the policeman off for a bath I searched his locker. This produced nothing, but under the bed I discovered a free sample of "kidney pills," containing methylene-blue. When I confronted the patient with this evidence he sheepishly admitted that he had found the pills in his letter-box the day before he came into hospital, and he "didn't like to waste them." (Yes, he *was* a Scot.)

* * *

When I borrowed a book from the B.M.A. library the other day, a piece of paper fell from the pages. It proved to be a filled-up football-pool coupon. I wonder, might it have lifted its owner, at one swoop, far higher than the highest consultant range (plus merit award)? Anyway, I am keeping it as a model; there's not much to be made as a peripatetic correspondent.

* * *

The accession of a ruler is traditionally marked by a general amnesty. Here is an obvious way for the new P.R.C.P. to celebrate his election: let all the most chronic Membership candidates—say those who have served a term of more than ten entries—be admitted without further prolongation of their suffering. The enactment of their release (including, of course, a symbolic casting away of cheque-books and examination papers) would be an unusually moving ceremony.

as part of the duty of those taking service in the National Health Service that part of their time should be given to one or other of the Fighting Services. It would not matter at what age that service was given and the time could be adjusted according to the medical officer's own work and the needs of the Service. At present the development of the National Health Service was only at the beginning. It was not at all certain at the moment whether the hospitals in this country were not employing more people than they required. For instance, about 82 medical officers were registrars at one large hospital in London. That was possibly at least four times too many. All doctors should be regarded as being in one pool to serve the national interest, whatever it might be and in whatever part of the world the service might be given.

Replying to the debate, Viscount ALEXANDER OF HILLSBOROUGH, Chancellor of the Duchy of Lancaster, did not specifically mention the medical points raised, but he gave a general assurance that there would be opportunities for further discussion during the forthcoming debates on the individual Services.

Midwives (Amendment) Bill

On April 5 in the House of Lords the Bill was read the third time and passed.

QUESTION TIME

Peckham Health Centre

Mr. JOHN COOPER asked the Minister of Health whether his attention had been drawn to the financial difficulties which threatened the closing down of the Pioneer Health Centre, Peckham; and if financial assistance would be forthcoming from his department to enable this centre to continue as a research institute under section 16 of the National Health Service Act, 1946.—Mr. ANEURIN BEVAN replied: As I understand that the centre is closed, the question of grants for research does not at present arise. The governing body of the centre have placed proposals for the centre's future before the London County Council and I am in touch with the council on the research aspect of these proposals.

Mr. I. N. MACLEOD: Whatever the London County Council propose, is the Minister aware that he has a direct responsibility to this House for the encouragement of research? Is he aware that those people best qualified to judge consider that the Peckham experiment was one of the most worth-while and exciting research experiments in the world? Mr. BEVAN: My officers will be delighted to receive from those who were in charge of the centre any conclusions on the research aspect of the experiment which they are likely to put before us. So far we have not received them.

Mr. OLIVER STANLEY: Is the Minister right in saying that there have been no discussions, even of an informal character, between those responsible for the centre and his officials? Is his Ministry not in possession of the new plans for research? Mr. BEVAN: What I said was that we would be very delighted to examine any conclusions reached on the research aspects of the centre, which has been in existence for many years. I will again make inquiries, but I do not think that we have had any concrete conclusions put before us.

Mr. WOODROW WYATT: Will the Minister act with some speed in this matter because the work of the centre is suspended for only three months? If it cannot reopen at the end of that period it will have to close for good. It is not sufficient to leave the matter to be settled by the L.C.C. Mr. BEVAN: There are two aspects of this matter. There is the health-centre aspect which first must be discussed by the local authority concerned, and there are the research aspects which are the concern of the Ministry of Health and the Medical Research Council. Both these aspects have to be considered together.

Major W. F. VERNON: In view of the fact that the research aspect of this work goes beyond the strictly medical field, will the Minister consider discussing it with the Advisory Council on Scientific Policy? Mr. BEVAN: It is because it goes directly beyond the medical field that it has some very interesting features about it. That is the claim it makes, that it is as much a social as a medical experiment. What we are trying to do is to assess the social significance of the centre as far as we can.

Advice on Contraception

Mr. ERNEST THURTLE asked the Minister under what National Health Service regulations doctors in the service were precluded from giving patients who applied for it information and advice about methods of contraception.—Mr. BEVAN replied: There is nothing whatever in the regulations to preclude this. Nor, however, is there any obligation on the doctor to do it unless he considers it necessary for purposes o medical treatment. Mr. THURTLE: Can the Minister say whether a N.H.S. doctor is justified in refusing to give this information on conscientious grounds? Mr. BEVAN: It is not my practice to interfere with the advice the doctor considers he should give his patient. I think it would be most unfortunate if we tried to intervene between doctors and patients in matters of this sort.

Private Importation of Streptomycin

Mr. JOHN GRIMSTON asked the Minister why special instructions had been given to the officers of H.M. Customs to prevent the private importation of streptomycin.—Mr. BEVAN replied: No substance to which the Therapeutic Substances Act, 1925, applies may be imported except under licence of my department. No licences to import streptomycin are being issued as British supplies are adequate for all home requirements, with a margin for export.

Ophthalmic Opticians and the N.H.S.

Mr. ANTHONY MARLOWE asked the Minister whether he proposed to employ ophthalmic opticians who were not ophthalmic medical practitioners in the National Health Service; whether he was aware of the concern among ophthalmic opticians that they were in danger of losing their livelihood; and if he would make a statement.—Mr. BEVAN replied: I assume the hon. Member has in mind the hospital eye service. 48 ophthalmic opticians are already employed whole or part time, and others will be engaged as the service develops. The ophthalmic opticians are aware of the situation. They know that what is in existence is a supplementary optical service. It is hoped that eventually the whole optical service of the country will be articulated through the hospitals where in the first place patients can be examined by ophthalmic surgeons.

Medicine and the Law

Wrong Labels in the Drug Cupboard

AT a recent inquest at Ramsgate upon the death of a six-week-old child, the evidence indicated that a fatal mistake had been caused by the unfortunate use of a drug carton. The doctor had prescribed 'Chloromycetin' in liquid form. A night nurse found three capsules in a packet marked "chloromycetin"; she took them to the night sister, who read the directions on the packet and handed her one of the capsules; she made it up into liquid form and administered the dose to the child. Next morning, she told the coroner, she was shown a flat white box containing chloromycetin in powder form which was also in the drug cupboard.

Another nurse explained at the inquest that, a few days earlier, she had found that the supply of 'Nembutal' capsules was getting low; she took out the three that were left in the bottle, in case they were required in an emergency, and sent the bottle to the dispensary; she put the three capsules in a carton marked "chloromycetin" and hid it at the back of the cupboard in a place different from that in which it was usually kept. The night nurse said she thought it rather strange when a yellow capsule came out of the carton; she asked if there was another box in the cupboard and was told that no other was visible and that the chloromycetin in powder form had been in that box before.

The incident was doubtless exceptional, but any fatality due to causes of this kind is one death too many. The hospital rule that drugs should be properly labelled when moved from one box to another must have been overlooked. The coroner, who recorded a verdict of death by misadventure, added the recommendation that the hospital staff should "brush up" their knowledge of fresh drugs.

and trial expeditions based on them, before we will be in a position to communicate fully to the people the benefits of medical knowledge.

General practice has raised itself a prophet, though how it will treat him remains to be seen. This is perhaps the most important aspect of the report, for rarely have I seen or heard anything like this reasoned statement of faith in general practice. It goes far to outweigh the brief consideration given to hospitals and specialists; for, while what we want in the end is a comprehensive and balanced view of our total task, this prophet will tell us that the specialists have many of his colleagues in their service already, and do not lack prophetic fire to help them. Nevertheless he is not free from a haunting longing for the "good" disciplines of hospital and medical school.

But are these so very "good" for general practice? Is not the almost total emphasis, from prevocational and even school days, upon the physical sciences, and the tangible realities of hospital practice, to the exclusion of the humanities and the social sciences, largely responsible? And must he not in the end, or better still in the beginning, win over those who control medical education, if he is going to save general practice? May not his improved conditions of practice (which should certainly be aimed at) remain a shallow expedient (like his refresher courses for G.P.S) in the face of an earlier and more fundamental error? Or is our society as a whole too hopelessly lost in materialism?

In considering his novel idea of locating specialist consultation services and facilities alongside the G.P.S in their health centres, one must be fair to the specialists. Can they be grouped in sufficient concentration to provide *their* optimum conditions in a series of necessarily very discrete centres designed for the welfare of the patient seeking general help?

Where also do we look for an army of general practitioners of the calibre indicated? Many men these days seek specialist practice as an escape from the more comprehensive discipline of general practice, and are not necessarily of higher calibre than those who might or do remain. It is more a matter of human capability, and unless things change greatly, I foresee great difficulty in securing, under any conditions, sufficient men to play the high part called for in his revived general practice.

As far as New Zealand goes, we are glad to accept the compliment of "good" practice even if with a wry face. I think the important words lie in his penultimate line—"within the existing concept of that service." The truth is that much of general practice is undertaken for financial reasons, without any special liking for or belief in it, and with the idea of as early an escape from it as possible. Certainly there has been no conscious thought or planning as to lines of demarcation between G.P. and specialist work in either urban or rural areas despite vast sums of public money being paid away in both fields. If the "gap" between G.P. and specialist is too wide in the U.K. it may well be too narrow in New Zealand.

These caveats should be regarded more as growls of pleasure on coming upon a more than usually meaty bone. I sincerely hope that both in the U.K. and in New Zealand this report will lead to the serious study of its subject-matter, and the devising of pilot plants for the solution of the problems. Lines of demarcation must be at least pencilled in, in the interests of function as well as of economy. They may well be found to lie in different positions in different countries and in different parts of the same country, and should be drawn by those who believe in G.P.S and also in specialists, and who seek to give both parties their best chance to serve the people in their different but both excellent ways.

Auckland, New Zealand. DOUGLAS ROBB.

SIR,—Most young general practitioners leave hospital with a good academic training and moderately high ideals. But we all know too well that twenty years of general practice brings far too many of us down to the level described by Dr. Collings. I hope that his cases were not really representative of the state of general practice in this country, but there is no doubt that there are far too many examples such as he describes, and it is a disgrace to our profession that any should exist at all.

To my mind the root of the matter lies in the width of the gulf between the conditions under which the medical student is prepared for general practice, and the actual conditions he finds there. I have argued this point a great deal with the staff in teaching hospitals, and their very sound point is that general practice cannot be taught, and that the best preparation for it is to give the student a thorough training in sound medical and surgical procedure; and it is then for *him* to apply it. This argument asks too much of the newly qualified doctor; he finds older men, apparently successful and respected, doing all the things he has been taught to avoid; he sees that they are sketchy and careless in their technique; and yet he finds that any effort on his own part to retain the high standard of skill that he has acquired is looked on as either cranky or presumptuous and often is not appreciated by the very patients he is trying to help. And because a good standard of medicine is expensive and does not bring in quick returns, his young enthusiasm gradually wanes, and he finds himself descending to the level of his predecessors and colleagues.

The remedy is threefold:

1. The teaching of general practice should be of primary importance in the medical schools. The attitude of the teachers must alter so that they feel their personal success or failure will be judged by the standard of the men who have been their students.

2. In order to teach general practice with real understanding, clinical teachers must at some point have been in general practice themselves for a sufficient time to understand the conditions under which the ordinary doctor works.

3. The student must be so prepared for general practice, and for the difference between what he is taught to expect and what he actually finds, that he will adopt a fighting attitude against poor medicine—that is to say, against hopeless conditions for the practice of good medicine. The young man must be taught to be sufficiently courageous, so that when he arrives at the converted shop with the drab battered furniture, the couch littered with dusty bottles, and the few rusty antiquated instruments, he will make a firm stand and say "I will not practise under these conditions; I will have more room, more light, more ancillary help, and better equipment." This is a battle which some of us have fought in our early days; and the harder the fight is to start with, the more worth while is the victory when it comes.

All this means that much more attention has got to be paid in the teaching schools to the advice of experienced general practitioners. At the same time, the Ministry would find it a good investment if they were to provide a scheme for financing young men who want to improve their premises and equipment; for there is no doubt that the cheapest and most effective way of dealing with patients *should* be by their family doctor in their own homes. It ought to be possible for domiciliary medicine to compete favourably with treatment in hospital for many conditions which nowadays are thought of as the sole prerogative of the specialists; but this will be possible only if the general practitioner is well trained and equally well equipped, and if—most important of all—he is able to devote adequate time to his patients. This of course means a smaller number on his list, and a correspondingly increased capitation-fee. And even then the Ministry guardians-of-the-money-bags would still find that cash spent on general practice could save more than its equivalent in hospital expenditure.

Great Dunmow, Essex. GEOFFREY BARBER.

Letters to the Editor

GENERAL PRACTICE TODAY

SIR,—Dr. Collings, as I read him, does not attack or decry general practice or general practitioners—far from it. What he says, in effect, is that the art and profession of general practice is sick and will die if something is not done to save *it*. His report makes bitter but, I believe, salutary reading; and I, at least, am grateful to him for making and to you for publishing it.

I hope and believe there is more good practice going on than he thinks, and a few of his implied suggestions perhaps savour of perfectionism, but the report rings true. Those parts I can check *are* true, and unless he is writing fiction we must accept as facts what he says he has seen. If we do that, we have no choice but to conclude that within the service set up by the State good general practice is suffering every possible discouragement while bad general practice is not only tolerated but is often an almost inevitable consequence of the conditions in which it is carried on.

Dr. Collings seems to have found the dysgenic effect of the meagre and almost uniform capitation fee less than might have been expected, but he describes how it cripples a man determined to do really good work and he gives ample evidence to show that the range of general practice is being steadily and, it would seem, deliberately narrowed. The G.P. is being excluded from the hospitals, and the trench dividing him from the specialist is being rapidly widened and deepened. Saddest, perhaps, of all, in a profession one of whose chief glories was what the Minister called "inbreeding," fathers are now discouraging their sons from following in their footsteps.

The *causæ morbis* are many and not all are recent. Some are no-one's fault but arise from increase of knowledge and elaboration of techniques; for some we are all to blame, but the apathy, cynicism, and dull-mindedness of the State—its indifference for nearly forty years to the quality of the service whose sponsor and paymaster it was—"stand out a mile." It cannot plead ignorance. Every F.M.R. and "continuation card" is marked "the property of the Minister of Health," so that successive Ministers had access to every panel doctor's clinical notes, and for years the Ministry's regional medical officers visited practitioners' surgeries. Either what Dr. Collings found is new and is peculiar to the N.H.S. or it is old and must have been reported. The fact is, I am sure, that the State, like Gallio, "cares for none of these things."

I myself heard Mr. Lloyd George in 1911 belauding the panel service he was creating and picturing the family doctor bringing hope, comfort, and help into the sickroom. Yet at that moment he was, as I now read, proposing to pay this son of Æsculapius and disciple of Hippocrates a capitation fee of four and sixpence.

The Ethiopian has not changed his skin. The State still protests that the family doctor is the backbone, keystone, or what-not of its health service; but, as Dr. Collings shows, the whole emphasis of the N.H.S. is on hospital and specialist services, with the local authorities' "personal health services" second and general practice nowhere.

I myself believe that general medicine is medicine at its highest, and that general practice is, or should be, practice at its best, but this is an article of faith. What I *know*, from daily experience, is that the patient or family treated by specialists, of whatever eminence and skill, without a general medical adviser come to grief. Specialists, whether in hospital or consulting-room, are no substitute for family doctors, and, if travellers can be trusted, countries in which a specialist iatrocracy has been established and G.P.s are counted an anachronism provide a really fearful warning. When, therefore, Dr. Collings concludes that "if the present trend . . . continues it must result in the elimination of general practice as an effective agency of medical care" he foretells, to my mind, both a medical and a national calamity. A crisis—and an irreversible crisis—is upon us. General practice, once destroyed, will not be re-created.

What can be done? Dr. Collings and others suggest apposite remedies, but who is to apply them? Can anyone suppose, does Dr. Collings himself seriously believe, that general practitioners, individually or collectively, can, in their present plight, apply them for themselves? The iron has entered into their souls. All too literally, I fear, "they haven't a hope." Besides, in the matter of organisation we have completely lost our freedom. Or are the local authorities or the present Ministry of Health to play *deus ex machina*? In current phraseology, "they haven't a clue."

I, at least, can see no hope save in a change of heart and a clearing of the mind in those who now control our destinies—press, Parliament, and Cabinet. What hope of that? I think there is a gleam. Linked to the crisis of general practice are two others—the crisis of the competing, unemployed, would-be specialists, fleeing from downgraded general practice, and the financial crisis of the N.H.S.

Bad general practice is expensive. It costs unnecessary medicines in unnecessary quantities, undeserved certificates of unfitness for work, and needless reference to costly hospitals. All this Dr. Collings makes clear. It also spreads demoralisation and chronic invalidism and destroys any hope that the citizen will, in the words of the Beveridge report, "accept the duty to be well."

For general practice and the practitioner the State cares nothing; for the specialist it does care a little; for its own pocket it is becoming quite anxious. The three linked crises are cumulative and must soon reach a climax. When they do it is just possible that the State will, for the first time, seek professional advice. We may have one more chance. If we do, might we not demand, what we have so long needed, a Minister of Medical Services? Much of our trouble comes from the confused thinking symbolised by misuse of the word "health" Dr. Collings shows clearly how that foolish, ambiguous term "health centre" is preventing the medical centre, which might save the situation, from taking shape; and it is surely obvious that public health, housing, and the National Medical Service are at least as distinct as Army, Navy, and Air Force, which have a Minister apiece.

Is it beyond hope that there might be found and appointed as first Minister of Medical Services a *statesman*—a man with good will to citizens of every class, with some understanding of the nature, functions, and limitations of medicine, some reverence for the art, and some understanding of the outlook, of the profession? No-one can restore to us "the years that the locusts have eaten," but such a man could at once give first-aid and could then begin, even now, to preserve and encourage the good, to discourage the bad, to supply what is lacking. He could set out to gain, by word and deed, the respect and trust of our humiliated and divided profession; he could abrogate some of his despotic powers and restore some at least of our freedom and our pride. Building carefully on such foundations as remain, he could construct by slow degrees the medical service the country ought to have, and he could leave for himself a name that would endure for generations.

London, N.W.3. LINDSEY W. BATTEN.

SIR,—Let us hope that Dr. Collings's unique report will begin a new era in our thinking about medical affairs in relation to public welfare. The strange thing is that we have proceeded so far and so fast without such essential information as is provided by this reconnaissance. Many more such reconnaissances will be needed, convictions for robbery with violence. For the war years only a summary of the criminal statistics was published, in which the number of convictions in regard to this crime were not distinguished from other forms of violent crime for which flogging cannot be ordered. I was therefore obliged to estimate the annual number of convictions for 1939 to 1945 on the assumption that they formed annually 37·32% of the number of such crimes known to the police—the average percentage during the fifteen years 1920–34. (This percentage must not be taken to mean that the guilty party is found in only 37% of the crimes annually committed; the apprehension and conviction of one guilty person very frequently brings to a conclusion the police investigation of *several* crimes.) Because this is only a " best estimate " the number of floggings in relation to the estimated convictions is of doubtful accuracy for the war period. But the *precise* flogging rates for 1946, 1947, and 1948 (the last relating to only 9 months but expressed on an annual basis) of 11, 16, and 7% of convictions conform to the pattern for the earlier part of the century which indicates that the amount of flogging ordered was independent of the volume of crime in the country.

To sum up, it is clear that the vast increase in robbery with violence during and since the 1939–45 war had no counterpart during or after the 1914–18 war. The recent increase is in fact something entirely outside the experience of the last 80 years. These are the facts as shown by the statistics. It is outside my sphere to attempt to specify to what cause or causes the increase is due. I suppose no-one can doubt that not one but many factors are contributory. But those who maintain that the upward trend can be reversed by the re-institution of corporal punishment as a deterrent must seek for justification of their beliefs elsewhere than in a study of the past relations between the extent of corporal punishment for robbery with violence and the prevalence of the crime. The recorded facts for the period 1860 to 1937 contain nothing to assist them.

PROPHYLACTIC INOCULATIONS AND POLIOMYELITIS

SIR,—The studies of Dr. McCloskey, published in your issue of April 8, and Dr. Geffen's article in the *Medical Officer* of the same date, are of outstanding importance; but their significance is more psychological than epidemiological.

One's first impression on reading the two articles is that evidence is given that poliomyelitis may be produced, or its risk increased, by anti-pertussis vaccination within the previous few weeks, but a careful reading of the figures shows that there is no shred of evidence for this assumption. They clearly show that persons who are inoculated with anti-pertussis vaccine and who subsequently develop poliomyelitis are very much more likely to have the paralysis show itself in the limb in which the injection has been made. They do not show that the injections produce poliomyelitis.

The psychological effects of the publication of these papers are, however, arresting, and excerpts have been quoted in the national press. The impression may be gained by the public that our immunisation campaigns are likely to be followed by an increased incidence of poliomyelitis. This may or may not be so. There is no information either for or against this view except the general impression, which is not a new one, that trauma, and in particular trauma due to tonsillectomy, may be an exciting cause. Dr. Geffen was certainly wise in giving publicity to the facts which he found, since the public are likely to react very unfavourably to any suggestion that facts adverse to immunisation are being withheld from them, and frank information on the ascertained facts is always useful.

The next step, however, is to carry out a statistical inquiry into the incidence of poliomyelitis in epidemic areas and at epidemic times in two groups of persons: (*a*) those who have not been inoculated within, say, the last three months against diphtheria or pertussis; and (*b*) those who have. Such an inquiry may present difficulties, and one cannot disguise the very great practical obstacles in the way of obtaining two large groups which are statistically capable of being contrasted. Nevertheless the importance of the subject demands that such investigations should be carried out.

This experiment might prove whether immunisation against diphtheria and pertussis was responsible for an increased incidence of poliomyelitis; but even if it did, it would not necessarily follow that immunisation campaigns should be either abandoned or modified. In the light of the new information one would have to assess whether the known risks of an increased incidence of poliomyelitis were or were not counterbalanced by reduction, or even eradication, of these two diseases, which between them are responsible for a heavy yearly mortality—a mortality greatly in excess of the death-rate from poliomyelitis.

The numbers of deaths from poliomyelitis and whooping-cough during the nine years 1940–48 were:

Poliomyelitis	1307
Whooping-cough	8508

Smethwick, Staffs.
HUGH PAUL
Medical Officer of Health.

THE HEART OF THE MATTER

SIR,—The " first Bevan lecture " in last week's issue contains much that is timely and pertinent, but the author is mistaken when he states that no medical school gives instruction to its students in the management of a general practice. A course for final-year students has been in the curriculum of the Manchester school for more than twenty years. This lectureship in medical ethics and conditions of medical practice was founded by the faculty at my suggestion, and has been held by such well-known G.P.s as L. Kilroe, of Rochdale, and the late T. A. Goodfellow, of West Didsbury. I know that it has been greatly valued by many men about to enter general practice.

Prestatyn, Flintshire.
E. D. TELFORD.

A CODE OF ETHICS

SIR,—As you mentioned on March 18 (p. 524), the British Medical Association has recently circulated a pamphlet on *Ethics and Members of the Medical Profession*. Primarily it is prepared for the information of practitioners who have qualified within the last ten years; but, although the pamphlet is dated 1949, the compilers seem to be unaware of the passage of the National Health Service Act, 1946. The initial paragraphs are excellent, pointing out the position of privilege which the doctor occupies in society and stating that " the justification for the freedom of medicine lies in the hands of those who practise it." But instead of applying these principles to the problems of today, the pamphlet then passes to the Hippocratic Oath, which may possibly have been written by Hippocrates 400 years before the birth of Christ. It is in its way admirable, but it is limited in its scope as a guide to conduct in 1950.

The need for a revised code of ethics is obvious, but perhaps the British Medical Association is no longer the most suitable body to sponsor it. I venture to suggest as one item an expansion of the Eighth Commandment of the Decalogue: " Thou shalt not acquire purchasing power without making an equivalent return in service to the community."

Liverpool.
HENRY H. MACWILLIAM.

CRIMES OF VIOLENCE

SIR,—Your comment on the article I wrote in 1938 revived my interest in the subject, and I have now attempted to bring up to date the statistical data originally analysed. The diagram gives a picture of the course of events between 1864 and 1948, during which period corporal punishment could be ordered by the courts to male adults found guilty of "robbery with personal violence."

The index obtained by relating the annual number of such crimes "known to the police"[1] to that section of the community who perpetrate them (i.e., to the number of males aged 15–54 in the population)[2] provides a measure of the annual volume of such type of crime more accurate than one in which the numerator is either the number of persons brought *to trial (some of whom will be found innocent)* or the numbers *found guilty (which would exclude some crimes for which no-one was punished)*. The best measure of the extent to which flogging was imposed each year as a penalty for this type of crime is the index obtained by relating the number of floggings ordered in any year to the number of persons convicted[1] in that year (i.e., the ratio of persons *ordered* to be flogged to the total number of persons that the courts *could* have flogged for robbery with violence).

These are the two indices depicted graphically, and I do not think the study of their relationship can be greatly objected to by reason of the known facts (*a*) that a small proportion of the convictions were quashed on appeal, and (*b*) that on health grounds some of the floggings ordered were not carried out. The ratio of floggings ordered to the number of convictions measures the extent to which the country's judges as a whole imposed corporal punishment.

The continuous line indicates that the volume of robbery with violence steadily declined from 140 crimes per million of the male population (aged 15–54) in 1868, to 10·4 per million in 1915. *During* the 1914–18 war the index rose to a peak of 21 per million in 1917, and *after* the war to 23 per million in 1921; but it declined to the lowest it has ever been (10·0 per million) in 1927.

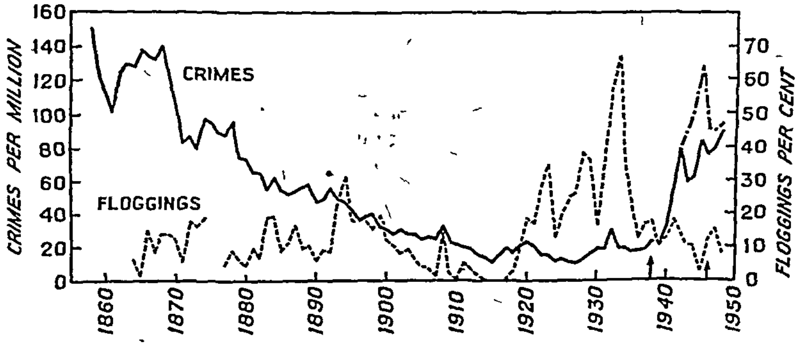
Now consider, in relation to this trend in the volume of crime, the dotted line showing the extent to which flogging was imposed. If flogging was imposed as a deterrent, then the logical sequence of events would be *a rise in the volume of crime, accompanied in the same year, or followed in the next, by an increase in the amount of corporal punishment ordered and with a fall in the volume of crime as a consequent.* Although an occasional instance of this sequence does occur, as in 1907–09, such instances are rare over the whole period. On the other hand if one takes, for example, the run of the figures over the last 20 years of the nineteenth century, it will be seen that the trend of the crime-rate was reasonably smooth and decreasing while the flogging rate fluctuated wildly and independently of the crime rate. During the 1920s or '30s when—apart from some increase associated with the trade depression—the crime rate was at a low level, flogging reached levels unprecedented in the previous 50 years. In 1933, 66% of those convicted were ordered to be flogged, but by 1936 the proportion had fallen to 12%. My original conclusion that flogging had been imposed more as a retributive than as a deterrent measure was based on a statistical treatment of such facts.

Now let us consider recent years. It has been suggested *that the current increase in robbery with violence originated during the trade depression of the early '30s.* The index I have adopted shows, however, that in 1935, '36, and '37 the rates were below the 1931 level of 18 per million, and that it was not until 1938 that a level above 20 per million appeared. Since that year the increase, although dramatic, needs to be carefully examined.

If for the war years the number of known crimes are expressed per million of the male *civilian* population (aged 15–54) a peak figure of 128 per 1000—as high as the 1864 level—is obtained for 1945. This, however, is fallacious since men in the Armed Forces *in this country* could also have been concerned in crimes of violence. The denominators of the ratios are too low and the rates consequently artificially high. The decline shown in 1946, when the civilian population only is used, is also fallacious and arises from the re inclusion in the denominator of those discharged from the Services. On the other hand, if the known crimes are related to the "*total* population"—civilian and non-civilian—the *denominator is* too high by the numbers of Armed Forces on *foreign soil*, and the rates therefore are artificially low. To some extent this is compensated for by the presence in the country of Allied troops who are not included in the "total population." But in spite of the doubt regarding the precise rates for the *war* years, it is clear that the level attained in 1948 of 95 per million of the population is matched only by rates which prevailed as far back as the 1870s. It took over 50 years to reduce the volume of crime from 95 to 10 per million. Yet it *has taken only 20 years to retrace the course*, and most of the deterioration has occurred in the eleven years 1938–48.

The crime rate of 89 per million shown on the graph for 1948 (or 94·6 if based only on the civilian population) was calculated from the figure of 1101 crimes of robbery with violence known to the police as recorded in the official volume of Criminal Statistics for that year.[3] The Lord Chancellor in the House of Lords stated on March 23 that in the first 9 months of the year 711, and in the last 3 months 267, *crimes* of robbery for which flogging could be ordered were known to the police. This is a total for the year of only 978. The difference of 123 between the quoted and published figures is doubtless capable of a simple explanation but cannot be ascertained from *publications* generally available. The figure of 1101 for 1948 is on all fours with the series *from which the diagram* was constructed. The Lord Chancellor's figure of 978 would give a rate of 79·1 per million of the total male population aged 15–54, whilst the figure of 806 which he added as the number known to the police for 1949 gives a rate of 69·4 for the following year. His figures therefore indicate a fall in the rate for 1949; but this may be but a chance annual fluctuation and it will be a few years yet before any conclusion can be drawn as to whether the peak of this wave of robbery with violence was reached in 1948.

The extent to which *flogging* was ordered attained its peak in 1933 when it was ordered in respect of 66% of



——— Number of crimes known to the police per million of the total male population aged 15-54.

-·-·- Number of crimes known to the police per million of the male civilian population aged 15-54.

.... Floggings ordered as a percentage of the number of convictions.

Note.—The figures for flogging between the two arrows are based on the assumption that the proportion of convictions to the number of crimes known to the police was constant at the average figure for the 15 years, 1920-34—namely, 37·32%.

3. Criminal Statistics 1948. Table D, p. 13. Class II. Offences against property with violence, subheading 34. Robbery 1101.

This is further illustrated by the investigations of Blackburn and Burke[3] who found that treatment with deoxycortone plus ascorbic acid did not result in a decrease of the circulating eosinophils, which would be expected if deoxycortone was oxidised to 'Cortisone' by ascorbic acid.

In order to throw further light on this problem, I suggest that it would be profitable to investigate the effect of other antioxidants chemically not related to ascorbic acid, such as glutathione,[4] cysteine, and *p*-aminosalicylic acid, and *p*-aminobenzoic acid, on the physiological action of deoxycortone. Glutathione is known to be intimately linked up with the functioning of the suprarenals. Moreover, all these substances have some properties in common with ascorbic acid. Their toxicity is extremely low. They inhibit the oxidation of adrenaline; they have a detoxifying action on a variety of noxious agents. *p*-Aminobenzoic acid is also capable of modifying the physiological response to hormones—e.g., combined stilbœstrol and *p*-aminobenzoic-acid therapy can result in anovulatory menses. In addition, improvement or alleviation in rheumatic conditions, asthma, chronic alcoholism, and morphine withdrawal syndrome have been reported as a result of *p*-aminobenzoic-acid therapy.[5]

The fact that improvement in all these conditions has also been obtained with A.C.T.H. would support the idea that *p*-aminobenzoic acid may act by exerting a favourable influence upon the disturbed endocrine equilibrium associated with the above diseases,[6] possibly by inhibition or activation of an enzyme associated with the metabolism of suprarenal hormones. The slight but undoubted improvement observed by Dr. Hallberg after administration of ascorbic acid or methylene-blue alone in patients with rheumatoid arthritis, as well as favourable effects obtained with cysteine, could be explained similarly.

CERVICAL RIB AND SHOULDER-GIRDLE

SIR,—In his article of April 1, Professor Stammers mentioned d'Abreu's[7] case of a girl with a cervical rib, in whom symptoms were precipitated by the falling of the shoulder-girdle after thoracoplasty. The following case shows the importance of the muscular support of the shoulder-girdle in preventing symptoms in an individual with cervical ribs.

A woman, aged 72, had a dissection of the glands of the neck done on the left side for a malignant growth. This resulted in damage to the spinal accessory nerve and paralysis of the trapezius. About two months later she began to get pain down the left arm, and after a further month noticed some weakness of the hand and impairment of fine finger movements. When seen three and a half months after the onset of symptoms, the left shoulder-girdle was definitely depressed, and the trapezius paralysed. There was moderate wasting and diminished power of the muscles of the thenar and hypothenar eminences, with some flexion deformity of the proximal interphalangeal joint of the 5th finger. Light touch and pin-prick were diminished over the ulnar margin of the hand and over the little finger. There were no vascular changes. Traction on the limb did not obliterate the radial pulse. A cervical rib was plainly palpable on the *right* side, but not on the left. There were no abnormal symptoms or signs in the right upper extremity. X-ray examination of the root of the neck showed well-developed cervical ribs on *both* sides.

In this case, the paralysis of the trapezius, with resulting depression of the shoulder-girdle, was the factor responsible for the onset of symptoms and signs of traction on the brachial plexus over a cervical rib.

The Radcliffe Infirmary, Oxford. ANDREW ZINOVIEFF.

CONGENITAL ŒSOPHAGEAL ATRESIA

SIR,—I was most interested in Dr. Donnelly's article of April 8. I think the most encouraging part is the evidence it affords that congenital œsophageal atresia is now exciting more interest than it has hitherto.

My own successful cases have now reached the total of 7, the first patient being now over three years old. The last successful case was in a premature infant who weighed 5 lb. 1 oz. at birth. In all of these infants primary anastomosis was carried out, and in all of them feeding is now normal, although in 2 there was a period when coughing on feeding was a complication.

Dr. Donnelly rightly gives prominence to the importance of early diagnosis, but I think this is not a difficult matter if the possibility of the condition is remembered, and for this purpose it is essential that pædiatricians and obstetricians should make a point of instructing the sisters and nurses under their charge to regard all cases of vomiting and cyanosis in infants as being due to this condition, until the contrary is proved. This preliminary diagnosis is best carried out with a soft rubber catheter passed through the mouth. If it is constantly held up at a distance of 10 cm. from the alveolar margin, the presence of an atresia is almost certain. The X-ray confirmation may well be postponed until the infant can be taken to a centre where facilities exist for experienced X-ray diagnosis and any subsequent operation. In fact, in the first two or three days the urgency is negative rather than positive. The great thing is to avoid persisting in attempts at feeding and keep the pharynx aspirated, to change the position constantly in order to aerate the lungs, and in addition to give penicillin. Fluid loss is not as a rule a feature at this stage, but should it be necessary to give fluid it is best to do so by the subcutaneous route.

With regard to the associated abnormalities, just as in congenital œsophageal atresia where other anomalies may be present, so also the converse may be true. This is illustrated by one of my successful cases, which must have been diagnosed earlier than any on record. One of my late house-surgeons, Mr. D. C. Perry, was called to see a newborn infant with an imperforate anus. With great acumen he thought that if the child had an imperforate anus it might also have an œsophageal atresia. He passed a rubber catheter in the way in which I had taught him and found that his suspicions were justified. He brought the child to me and we were able to confirm the diagnosis radiologically; and I carried out an operation successfully twelve hours after birth, and before any attempt at feeding had been made. The child's recovery was uneventful. I feel that this illustrates the fact that early diagnosis can be achieved if the possibility of the lesion is brought widely to the notice of those concerned with the care of infants soon after birth.

Department of Surgery,
Postgraduate Medical School of London. R. H. FRANKLIN.

SIR,—In his article on congenital œsophageal atresia Dr. Donnelly does well to draw attention to the great difficulties in successfully treating these infants, particularly those whose entry into hospital has been delayed.

We rely on the general practitioner and the midwife to bring the patients to our notice early, and they need to know the earliest signs. In advocating "very early diagnosis" Dr. Donnelly mentions first that "signs of dehydration are usually evident soon after birth," but if we present this sign to the general practitioner as the criterion for admission we are going to defeat our purpose. It is *not* an early sign; it is a late one.

COPIES OF APPLICATIONS

SIR,—May I ask that the regional boards be more modest in their demands for copies of applications for appointments. I am convinced that no "short-listing" subcommittee could possibly require more than three copies of an application in the first instance, and that no candidate would begrudge the balance of ten or fifteen should he be selected to appear for interview. I am engaged at present with twenty-six copies of applications for three appointments.

CANDIDATE.

ŒSTROGEN THERAPY IN MENSTRUAL AND PREGNANCY DISORDERS

SIR,—Your leading article of April 1, adopts a welcome tone of scepticism. It is, however, a pity that this scepticism has so closely approached obsession as to have led to misrepresentation and misquotation of my paper [1] to which you refer in some detail.

There are two main reasons why the daily dose of stilbœstrol advised for the control of prolonged uterine bleeding is given as 2–5 mg. In the first place, this has proved sufficient in most of my patients, and experience since the above-mentioned report was written has not changed my view; in the second place, by using the minimal effective dose the incidence of toxic reactions to stilbœstrol is kept to a low figure. Parenthetically, I have not found that ethinyl œstradiol, in effective doses, is much less liable than stilbœstrol to produce toxic effects. Moreover—and this you omitted—the further advice is given that the dosage should be doubled if (and here I quote verbatim from my paper) "after 48 hours there is no sign of improvement." This expedient has seldom proved necessary, and when used has seldom failed.

It is stated that I have claimed 100% success for the treatment advocated in cases of prolonged and excessive irregular uterine bleeding. Such a claim would clearly be ridiculous and the statement, as well as the sentence preceding it, is a gross misrepresentation. In point of fact, no claims of any sort were made, and in this particular group of patients evidence for the occurrence of ovulation following treatment was reported in 8 out of 19 *patients, not 8 out of 8 as is suggested.*

I did not find "secretory endometrium in all of . . . 8 cases in which initial biopsy showed a proliferative endometrium or cystic glandular hyperplasia." In case 1, for example, which is reported in detail, an initial proliferative biopsy was found in the 13-year-old subject of puberal menorrhagia, but no post-treatment biopsy was taken and it was quite obvious that ovulation was *not* occurring after treatment. In case 9, aged 27, also reported in detail, a proliferative endometrium was obtained after treatment which had followed the original Hamblen technique and relapse soon occurred; a second course following the modification I have described was, however, succeeded by a secretory endometrial biopsy and the patient remains well.

It is also deprecated that the ages of the patients and the interval between pre-treatment and post-treatment biopsies were not given. Actually, the ages and certain summarised details of all the cases mentioned in the report are given in tables, which, as was explained in a footnote to the paper, could not be published on account of restriction of space but which are available on application to anyone interested. The interests of accuracy might have prompted you to inquire for a copy of these tables.

Finally, it is suggested that puberty bleeding and the "metropathic" type of maturity bleeding are likely to undergo spontaneous remission, the inference being that such an occurrence could explain the apparently successful results of treatment. Certainly spontaneous remissions occur; an example is described in my paper. But in my experience this has been exceptional possibly because the majority of the patients referred to me have already had symptoms extending over many months or years (4 months to 15 years in the group of cases reported) and have already failed to respond to treatment at the hands of other doctors. In cases such as these it seems at least as reasonable to suggest that a course of treatment (which, incidentally, relieves the patient of her symptoms at once) followed by apparent cure has played some part in producing the cure as to claim that the "cure" is no more than a spontaneous remission.

University College Hospital,
Obstetric Hospital,
London, W.C.1.

G. I. M. SWYER.

*** We were confining our comment to the 8 cases in which (we believed) biopsy was performed both before and after treatment. That there were 8 cases of this kind was suggested by the following passage in Dr. Swyer's paper:

> "Endometrial biopsies were taken before treatment in nine cases; they showed a proliferative type of endometrium in seven cases and cystic glandular hyperplasia in two. In no case, therefore, was evidence of ovulation obtained. Biopsies were taken after treatment in eight instances (excluding a case of spontaneous cure) and showed secretory changes in seven of them. The single instance of a post-treatment proliferative biopsy . . . followed a 'C.D.' (constant dosage) course of treatment, and relapse occurred three months afterwards; a 'D.S.—I.E.' (diminishing stilbœstrol and increasing ethisterone dosages) course of treatment was then used, and three months after the end of this second course the endometrium was found to be secretory."

It is now clear, however, that the before-treatment and after-treatment biopsies were not all performed on the same patients, and our suggestion of 100% success in this series therefore falls to the ground. Our misinterpretation of the passage in question was, we think, excusable; but we regret the wrong impression given.—ED. L.

RESEARCH ON ARTHRITIS TREATMENT

SIR,—The successful treatment of rheumatoid arthritis with deoxycortone plus ascorbic acid, introduced by Lewin and Wassén,[1] raises at once the question as to the mechanism by which ascorbic acid is able to modify the physiological response to deoxycortone so profoundly. Although there is little doubt that ascorbic acid plays an important part in steroid metabolism, it appeared to me unlikely—especially in view of the high dose required to produce clinical improvement—that this effect could be entirely specific to ascorbic acid.

The paper by Hallberg [2] has confirmed my opinion. Objections may be raised, however, against the rôle of a biological oxidising agent assigned to ascorbic acid in this article, unless it is assumed that oxidation of ascorbic acid preceded that of deoxycortone. In this case therapy with deoxycortone plus dehydroascorbic acid should give equally good results. Moreover, a much smaller dose of dehydroascorbic acid would probably be required, since it can hardly be postulated that all the ascorbic acid used in the Lewin and Wassén therapy is oxidised. An alternative hypothesis would be that ascorbic acid acts by suppressing heavy metal inhibition of an oxidase involved in steroid metabolism.

The fact that identical clinical results have been obtained with a reducing agent (ascorbic acid) and an oxidising agent (methylene-blue) seems to indicate that the biological reactions involved in the modification of the physiological response to deoxycortone are complex.

unfortunately largely maintained and spread among the population because of this feature, which is too often overlooked. The gonococcus "hibernates" in the uterus and adnexa, and therefore penicillin by itself does not usually cure women.

Treatment by dilatation of the cervix and a glycerin drain, followed by systemic penicillin, allows the infected discharge to pass out from the uterus and adnexa; and it is usually possible in such cases to find or culture the organism at the same time. These methods of treatment of course necessitate the provision of trained personnel and facilities, which are not at present available at some local clinics.

London, W.1. G. M. SANDES.

SYMPATHECTOMY IN HYPERTENSION

SIR,—In their article of April 8, Professor Platt and Dr. Stanbury express the belief that "the majority of cases of essential hypertension can . . . be divided into two classes—namely, those which are too mild to warrant the use of this serious operation, and those which are too severe, too old, or too arteriosclerotic to benefit from it." They conclude that "sympathectomy should very rarely be advised in hypertensive disease."

Our conclusions are very different. They are based on a preliminary survey of the first 56 patients who have undergone thoracolumbar sympathectomy for hypertension in the surgical professorial unit at Liverpool. These have been followed up for periods varying from 6 months to 3 years. A further 40 operations have been performed on 27 patients who have been followed for shorter periods. We have also had access to the records of 23 patients on whom Mr. Ronald Edwards has performed an extended form of Peet operation.

For the sake of comparison with the article quoted, we may conveniently think of three groups, representing three stages in the development of the syndrome.[1] Concerning the intermediate group, we agree that operation offers the only hope of relief and may sometimes prove curative. In the advanced group, which Platt and Stanbury would turn down, we have found some of our most grateful patients. Their lives may not have been prolonged much, if at all, but their lives have at least been made worth living. In the early group, in which we have picked up all too few patients, we hope that surgery may in an appreciable percentage of cases arrest the disease in its labile developing stage. Whatever else may be in dispute, it must be agreed that no other remedy is available and that the disease is progressive. If the late cases must be denied because they are too late, it seems a little hard to refuse the early ones because they are too early!

Platt and Stanbury state that Bechgaard[2] and Burgess[3] have shown that moderate hypertension may be associated with no significant increase in mortality. This statement is true when applied to Bechgaard's group as a whole, but it is not true of the patients who are under 50 years of age. In these the mortality-rate was $2^1/_2$ times the normal in women, and 9 times the normal in men. (The figure in men is so high because the group includes some patients with glomerulonephritis, all of whom died; but even if these are excluded the figure is still high.) Burgess states that in hypertensive patients below 50 the average length of life is over 15 years, which is 11 years below their normal expectancy, and that "the younger the patient at the time when the hypertension develops, the less likely he is to live out his full life's span."

We no longer regard the operation as being unduly serious. In our series of 56 cases (which includes *all* those operated on in the period of review) there have been 3 operative deaths. The first was known to be a desperate chance, which was deliberately accepted. The second was early in the series, when we failed, from lack of experience, to recognise acute cardiac failure beginning just before the operation. Both cases were in the advanced group. The third was a girl, dying from chronic nephritis, who had a blood-urea of 400 mg. per 100 ml. at the time of operation. Before death it was not clear whether she had nephritis or malignant hypertension, and the grave risk was taken because it was believed that she would not live many days as she was. In the last 40 operations (performed in the last six months) there has been no operative death.

Although we should like to see a significant fall in blood-pressure in all our cases, we do not, at present, expect it or even necessarily regard it as desirable. We certainly do not regard it as the sole objective or criterion of success of the operation. In the early cases it should be so, but in the intermediate and late we should be grateful for, and content with, symptomatic relief.

We believe that the main contra-indications to operation are: (1) mental confusion, indicative of cerebral vascular changes; (2) grossly impaired renal function; (3) certain forms of cardiac failure; and (4) age. There is no benefit to be obtained from operating on patients over 55 unless they have severe incapacitating headaches. With certain further reservations we believe that all other cases of essential hypertension should be accepted for thoracolumbar sympathectomy.

Department of Surgery, CHARLES WELLS
University of Liverpool. RICHARD WELBOURN.

SIR,—Professor Platt and Dr. Stanbury, in their excellent paper, state: "*it will thus be seen that our series is difficult or impossible to compare with that of any so far published.*"

In a paper of ours published some ten months ago,[1] in which the case material was very similar but the number of cases smaller and follow-up shorter, the results of sympathectomy were of the same nature as those of Platt and Stanbury.

Westminster Hospital, London, S.W.1. J. C. HARLAND.

SIR,—The important problem in the surgical treatment of hypertension is the selection of patients in whom sympathectomy will give not only symptomatic relief but also a significant fall in blood-pressure. So far the effect of sympathectomy on the blood-pressure cannot be prejudged: there is no correlation between preoperative pressor and depressor tests and the post-operative blood-pressure, and while it is likely that the best results will be obtained in patients under 50 years of age, yet sometimes an excellent result is produced in an older patient (56 years).

The conclusion of Professor Platt and Dr. Stanbury that sympathectomy should very rarely be advised in hypertensive disease is an overstatement. Even accepting the fact that the blood-pressure will be reduced in only 10–20% of patients over a period of years (a higher degree of success than in the surgery of cancer of the stomach), symptomatic improvement is so frequent that these patients are a very satisfied group. Relief of headache can be promised and in some cases protection from blindness, yet Platt and Stanbury seem almost to grudge the favourable report of their patient in an oxygen tent.

The operative mortality, if a recent stroke or a recent coronary thrombosis be excluded, is small. The Adson's sympathectomy, which upsets the patients no more than an interval appendicectomy, is adequate for the relief of headache and operation on one side may be sufficient for this purpose. When a wide removal of the sympathetic system is made in an attempt to lower the blood-pressure, this can be done with the same morbidity

I feel that in Dr. Donnelly's article the emphasis is misplaced, and that attention should be given first to the drooling of saliva, which is almost diagnostic of the condition. Secondly, many of the infants have a cyanotic tinge, quite apart from cyanotic attacks, which may be infrequent. Thirdly, they often have a feeble, spluttering cough as the mucus spills over into the trachea. These are the features that should lead us to suspect atresia of the œsophagus even before the first feed. This suspicion is confirmed when the infant is offered a little glucose and water, causing regurgitation and a cough. It is at this stage, within twelve hours of birth, that the child should be sent to hospital.

With regard to the multiple-stage operation, I think that, in fairness to Swenson, it should be made clear that he abandoned this method at the beginning of 1947 and now has well over 30 survivors to his credit by the one-stage operation.

The Children's Hospital, Sheffield. R. B. ZACHARY.

SIR,—Dr. Donnelly's plea for early diagnosis of congenital atresia of the œsophagus will have the support of everyone who has either made or missed the diagnosis. As a resident at the pediatric department of the University of Minnesota I had the privilege of looking after some of Dr. M. L. Leven's cases, and I have seen a few examples of the condition since. This experience prompts me to comment on Dr. Donnelly's paper.

He opens with the statement that "the prognosis . . . is now exceedingly bad," and his experience illustrates this point. But it should be remembered that until recently the common form of this disorder (to which his five cases belong) was incompatible with life. Advances in pædiatric surgery now offer a fair chance of survival (57 survivors out of 113 cases operated on at the Boston Children's Hospital in the past eight years[1]). In this chance of survival lies the justification for what is still very hazardous major surgery. The prognosis is very much better than it was.

I must disagree with Dr. Donnelly's statement that "signs of dehydration are usually evident soon after birth." In my experience dehydration is not a conspicuous feature, nor is it to be expected in the first day or two of life in these circumstances. Dehydration was noted in only one of Dr. Donnelly's cases (case 1, aged 5 days, weight loss 5 oz. from birth weight of 6 lb.). If the diagnosis is made early it will be made before significant dehydration has developed.

The diagnosis can be made with some certainty on clinical grounds alone. In addition to the features mentioned by Dr. Donnelly, a direct question to the nurse will usually elicit the information that she has noticed an uncommonly large amount of regurgitated mucus and saliva in the cot. This suggestion of failure of swallowing can be tested by attempting to pass a stomach tube: arrest of the catheter at a point short of the stomach and at the same distance each time the passage is attempted, is presumptive evidence of œsophageal atresia. The resonance of gas in the abdomen adds support, for commonly the atresia is associated with fistulous communication between the trachea and the lower œsophageal segment.

The diagnosis is confirmed, as Dr. Donnelly states, by radiology, though I would hesitate to use more than 1 ml. of iodised oil; 0·5 ml. is usually sufficient, and a good lateral film and the good fortune to find air present in the upper segment *may* make even this unnecessary. The preference for iodised oil as the contrast medium might have been emphasised by stressing the danger of aspirating barium into the lungs.

In my experience, postural drainage is preferable to repeated intermittent pharyngeal suction; all too soon the latter is followed by blood tingeing the mucus. I prefer to raise the foot of the cot and to nurse these babies on their sides (the prone position recommended by Dr. Donnelly seems to me to rest too much of the child's weight upon his thoracic cage); suction is only needed as a first-aid measure when drainage fails. I feel happier if these patients are in some simple type of oxygen tent, provided it does not impede first-aid measures for cyanotic attacks. Not all the atelectasis is necessarily due to aspiration pneumonia, for some of the radio-opaque areas in the lungs may never have expanded; I favour the use of 5% carbon dioxide in oxygen for 5 minutes every hour or so when the airway is clear, believing that these "breathing exercises" have value.

Finally, Sir, the diagnosis having been made, and postural drainage and parenteral fluids having been started, may I, too, utter a plea for these children? It is that the next step should be to transfer them to a surgeon who has already some experience of the operation or who has at least familiarised himself with descriptions of the technique and practised it upon the cadaver. (Dr. Donnelly's cases had the benefit of such a surgeon.) When the diagnosis is made early, extra time can be well spent on preparing for the operation. In an oxygen tent, with a sensible nurse in attendance, these babies travel well; they arrived in Minneapolis in good condition after journeys of five hundred miles or more. Even in the most skilled hands there is a surgical mortality of some 50%. Often in deciding to operate at all there will be some special feature in the case —the first child of an elderly mother, for instance— to make that infant's life more valuable than most. As in a comparable field of surgery—that of congenital heart-disease—opportunities to acquire this particular skill are not common and it would seem well to concentrate that skill in the hands of a few.

Ipswich. R. M. MAYON-WHITE.

PENICILLIN FOR GONORRHŒA

SIR,—Your leading article last week and the paper by Mr. King and his colleagues are most timely. They underline what has been suspected by many workers in this field and has been causing anxiety. The general public have been deceived by writings in the lay press and elsewhere. Those unfortunate people who acquire gonorrhœa or other pyogenic infections are convinced that these diseases are trivial and easily cured.

It is interesting that apparently 1788 infected men attended the Whitechapel Clinic, while only 481 women were dealt with over a similar period of time; this means that 3–4 times as many men as women sought advice. Probably most areas would report similar findings. Twenty-five years ago a corresponding ratio was observed at the London Lock Hospital: the inference obviously being that more women are untreated than men.

In many smaller departments an adequate pelvic examination in women is not carried out, owing mainly to the fact that clinic officers are often not trained in proper methods of gynæcological examination. The initial symptoms and signs of infection are less obvious in women, and furthermore many women refer any deviation from the normal to some alteration in menstruation. Thus it is very rare for a woman to seek advice until the infecting organism has spread upwards to at least the lining membrane of the uterus and tubes. By this time external manifestations may have practically disappeared, and smears and cultures from endocervical exudates will show no diagnostic features. The woman, if she seeks advice at all, may be reassured after somewhat cursory examination, and she remains potentially infective. Gonorrhœa and other pyogenic infections are tuberculosis do not suggest that the effect of pregnancy on the group as a whole is adverse." But the group belongs to the decades of child-bearing, in which the mortality and morbidity rates for females are highest. In his stimulating paper, he discusses the complication of pregnancy by pulmonary tuberculosis; and preventive medicine is not part of such an investigation. But his findings, unqualified by a reminder of the infectious nature of tuberculosis, are dangerous. On the day of publication, one of the daily papers with a wide circulation was quoting him and almost inviting the tuberculous to forget their fears and raise a family.

Public Health

Suspected Smallpox on a Vessel

WHEN the S.S. *Cilicia* arrived at Liverpool from Bombay on April 16, a suspected case of smallpox was removed to the port isolation hospital. The patient, a boy, aged five years, who was travelling with his mother in a first-class cabin, developed a rash on April 10 and was at once isolated in the ship's hospital as a suspected case of smallpox. The 320 passengers, who had all been vaccinated, were medically examined and allowed to proceed to their destinations under surveillance, the medical officers of health of the areas to which they were going being informed. The diagnosis has not yet been confirmed, but all precautions have been taken as though the case were one of smallpox.

Smallpox in Glasgow

Glasgow was declared free of smallpox last Monday.

Influenza in the U.S.A.

During the 11th week of this year (March 12–18) 29,036 cases of influenza were reported in the U.S.A.; the corresponding figure for 1949 was 3780. The cumulative total of cases in the first 11 weeks was 144,982, compared with 49,087 in 1949 and 169,936 in 1946—the year with the heaviest incidence in the last quinquennium. Texas and Virginia are the States most seriously affected. The disease is, however, not especially severe. Laboratory reports suggest that some of the cases are due to A-prime, or a closely related, virus.

Statistics for Scotland in 1949

According to provisional figures,[1] the birth-rate in Scotland during 1949 was 18·5 per 1000; this is 0·9 below the rate for 1948 and also 0·9 below the average for the five preceding years. The stillbirth-rate was 27 per 1000 live and still births, compared with 29 in 1948. The death-rate was 12·3 per 1000. The infant-mortality rate was 41 per 1000 live births—the lowest ever recorded in Scotland. The neonatal death-rate was 23 per 1000—also the lowest recorded. The maternal-mortality rate was 1·3 per 1000 total births—only half that experienced as recently as 1945. The death-rate from tuberculosis (all forms) was 67 per 100,000, which was 9 below the average of the preceding five years, and was approximately the same as that for the years immediately before the late war. The death-rate from respiratory tuberculosis was 59 per 100,000 (3 below the five-year average), and from non-respiratory tuberculosis 8 per 100,000 (7 below the five-year average).

THE FOURTH QUARTER

The birth-rate in the fourth quarter was 17·4 per 1000 of the population—a lower rate than any experienced since the year 1945, but higher than for any fourth quarter in the five years before the late war. The death-rate was 12·2 per 1000. The infant-mortality rate was 44 per 1000 live births; and the death-rate from tuberculosis (all forms) 63 per 100,000.

Obituary

THOMAS WILSON

M.D. LOND., CH.M. BIRM., F.R.C.S.

Dr. Thomas Wilson, emeritus professor of obstetrics and gynæcology in Birmingham University, died at Malvern on March 23. Though he was on the eve of his 90th year, his activity of mind was unimpaired, and on the previous day he took his customary walk.

Born at Cumnock in Ayrshire in 1861, Wilson went to Wolverhampton School. In 1878 he entered University College, London, and he completed his medical education at University College Hospital. After receiving medals in pathology and hygiene, he took his M.B. in 1883 and his M.D. two years later. As resident medical officer at the National Hospital for Nervous Diseases, Queen Square, in 1886, he worked under Hughlings Jackson, Ferrier, and Horsley; indeed, only financial considerations appear to have prevented him from taking up neurology as his life's work. However, after a year as ship's surgeon with the P. & O., he settled in general practice at Cannock.

In 1890 he was appointed gynæcological surgeon at the Wolverhampton General Hospital, and while attending to his duties there and to his general practice, he passed the primary F.R.C.S. In 1893, after election as honorary assistant obstetric officer at the General Hospital, Birmingham, he passed the final F.R.C.S. and entered consulting practice in Birmingham. In midwifery Wilson had already had considerable experience in London, at the Rotunda Hospital in Dublin, in general practice, and at Wolverhampton. Operative gynæcology at this time was the field in which Lawson Tait had already achieved fame through his work in Birmingham, and Wilson took a keen interest in developing this department at the General Hospital under his more obstetrically minded senior, Edward Malins. When Wilson, in his turn, retired in 1921 the department came under the care of his brilliant junior, Beckwith Whitehouse.

In the teaching of practical midwifery and the treatment of difficult labour Wilson rendered great service to patients, medical students, and midwives in Birmingham. When the Midwives Act was passed in 1902, requiring that all midwives should be qualified by proper training and examination, he seized the opportunity to urge the establishment of a maternity hospital where cases of difficult labour could be treated as inpatients and in association with which student midwives, and medical students, could be trained. The Birmingham Lying-in Charity, which provided district midwives for attendance on poor women in labour in their homes, and upon whose staff Wilson had served as a consultant for some years, was reconstituted largely through his influence, and, with the enthusiastic support of generous citizens, the Birmingham Maternity Hospital was opened in 1907. Wilson served as senior surgeon for the first 15 years of its existence, and the high standard of obstetric practice and teaching which the hospital at once achieved was largely due to his guidance.

In 1903 he was elected honorary obstetric officer at the General Hospital, and he was also consultant to many hospitals in Midland towns. From 1912 until 1924 he was professor of obstetrics and gynæcology in Birmingham University, and at various times he served as examiner at London, Manchester, Bristol, Leeds, and Birmingham universities. As a teacher he was a clear and careful lecturer and a frank and honest exponent of the difference between that which was proven and that which was a guess. In days when the utterances of distinguished clinicians, based upon their investigations at the bedside or upon the operating-table, received possibly more ready acceptance than the findings of workers in laboratories and post-mortem rooms, Wilson never forgot his pathological training; he maintained a pathological laboratory near his hospital department and a small laboratory at his home, where he regarded pathology as his hobby. He contributed many articles and chapters to medical journals and textbooks, and his work on pelvic inflammation in the female, described in either transpleurally or retropleurally. The development of Raynaud's phenomena in the hands will be avoided if the third thoracic ganglion is removed. In my series of about 200 cases subjected to the Smithwick, Adson, or Grimson procedure or removal of the thoracic ganglia and splanchnics, the same immediate fall of blood-pressure has been produced—sometimes the diastolic has been as low as 70 mm. Hg for 3 days, and no complication has arisen from this sudden drop—and there are more sustained falls of blood-pressure when the denervation has been from the sixth thoracic to the third lumbar ganglia, including the splanchnics. The adverse effects which Platt and Stanbury describe occur in only some patients, and the patient will always say he would rather have the temporary disability than his previous symptoms.

[1] Quarterly Return of the Registrar-General, Scotland: Births, Deaths, and Marriages Registered in the Quarter ended 31st December, 1949; also Preliminary Return for the Year 1949. H.M. Stationery Office. Pp. 32. 1s.

Whether to recommend sympathectomy for hypertension depends on what is expected of the treatment. If it be accepted that sympathectomy will not yield Cato's pleasant old age but that it may allow many, with Horace, to enjoy the fleeting hour before boarding Charon's skiff, then operation will be advised not infrequently. The following two examples show excellent and encouraging results:

A hypertensive man, aged 42, unconscious and having fits unless given 'Sodium amytal,' improved dramatically after an Adson-type sympathectomy carried out at the relatives' request, and 14 days later withstood a Smithwick-type operation on the other side. He returned to work free of headaches and with well-marked regression of retinal changes.

A hypertensive woman, aged 52, incapacitated by severe headaches, had to lie in bed since dizziness developed as soon as she sat up. After a bilateral Adson operation she was able to return to an active public life, free of symptoms.

Leeds. H. S. Shucksmith.

WAR

Sir,—We cannot, and need not try to, find culpability for war to be "equally shared." But does this matter? What we have to do is to prevent it.

The discovery of positive law has shown mankind a practical way out of this sort of difficulty. And now, as Dr. Stewart well has it, "Force within Law" must become "Force within World Law."

Is it not our duty, as world citizens that would be, to try to set aside German "guilt" (and Russian, or American, or British) in facing that harder, finer task of creating a great Unity? This will mean fighting for the right, but it will be a World Right and not a national "right."

A properly constituted World Order System will be capable of combating any -ism (of Left or Right) that might wish to threaten it. This means peace instead of war.

Edinburgh. Rantyard West.

PREGNANCY AND PULMONARY TUBERCULOSIS

Sir,—Dr. Midgley Turner's excellent article of April 15 calls for a reminder to all of us that there is a public-health problem also in the relationship of the child and the tuberculous mother.

The implication of his investigation is that active pulmonary tuberculosis should no longer be considered a contra-indication to full-term pregnancy. That is the clinical view. But the very important question of the future health of the baby must also be considered. Statistics show that tuberculosis develops in contacts in a significantly higher proportion than in non-contacts; and what closer contact is there than that of mother and child? Is it right to decide to expose a potential child to this known high risk?

There is evidence that there is a personal or inherited factor of poor resistance—that there are family strains with weak resistance to tuberculosis. That this lower resistance is not necessarily apparent in every child of a family should not fog the main issue. It is surely undesirable to perpetuate a strain with evident poor resistance.

Preventive medicine and social and economic problems meet in the home, and it is there that the tuberculous mother and her up-to-now uninfected infant face years of difficulties, worry, and risk.

There are two kinds of tuberculous mothers: the first are those unfortunate women, at best only improved by sanatorium treatment, whose sputum remains positive; the second are those whose disease can be apparently arrested by modern treatment. In the first, surely there is no problem of decision; it cannot be desirable for her to have a child. So often the tragedy is that she already has one or more children, or is pregnant, when she first comes to clinical notice. If the pregnancy is terminable in these cases, in which pregnancy is a risk to life, early termination is indicated. If the patient is allowed to go to term, the ideal is foster-parenthood—not a source of joy to the mother, or an ideal plan for the child. Otherwise, if the parent with a positive sputum is to live at home with her child, all the education and conscientious observation of the rules of personal hygiene must inevitably fail from time to time; it takes few enough virulent bacilli to do the damage. The controlled households in tuberculosis colonies may suggest that this breakdown is infrequent; but most households are not in colonies, and the incidence of tuberculosis in families proves that there is a breakdown.

It is in the second type of case that controversy may arise. Such a woman, after treatment of open disease, may have arrived at the stage of quiescence. This, however, is always a vague state, and modern methods in the culture of the bacillus have proved how difficult it is to achieve true quiescence. Clinically there is still a significant proportion of subsequent breakdowns in cases apparently proved quiescent. In the present position of treatment, it is not possible to say to a woman that she is permanently and irrevocably cured and can live a full life. Instead, she is to be told that, whilst she is not to be a hypochondriacal invalid, her life must be disciplined and planned—no easy task in the industrial worker's homes or those of the middle classes. Personal hygiene will have been taught to her, and even if she is apparently sputum-negative on leaving sanatorium, her baby (if she has one) will be a potential guineapig all the time. If she is a sincere woman we are putting a great burden of worry on her shoulders; she will watch that child, and perhaps subsequent children, for the stigmata of her own infection.

The second worry of the mother is the avoidance of doing too much. The care of a baby, and more so that of a growing child, is a day's work and sometimes a night's work. Added to this is the maintenance of her home, and as a wife, her desire to enter as much as she can into the full enjoyment of a normal and social life with her husband—all a strain on quiescent tuberculosis.

The recently published findings on the state of the population in this country indicate the need of more children, of healthy stock; but it is very doubtful whether it is desirable to increase the population from known tuberculous stock at continued tuberculous risk. There are still fortunately a majority of healthy young people as potential parents.

Clinically, like my colleagues, I get great personal satisfaction when a pregnancy has to go to term for good reasons, and the mother comes through with a healthy baby and apparently quiescent lung lesions. The inevitable has been met with success; but should the risk be run again? Ideally the procedure is not complete unless the mother has been voluntarily sterilised to avoid a second crisis.

To return to Dr. Turner's series. He says that "survival-rates for the groups with active pulmonary

University of London

Dr. M. L. Rosenheim has been appointed to the chair of medicine at University College Hospital Medical School.

Dr. Rosenheim, who is 42 years of age, was educated at Shrewsbury School and St. John's College, Cambridge, where, in 1929, he took a first-class in part I of the natural sciences tripos and was elected to a foundation scholarship. At University College Hospital he held Goldsmid and Filliter exhibitions and he was awarded the Fellows and Tuke medals. After taking his B.CHIR. in 1932, he held house-appointments at U.C.H., and spent a year in research in the departments of bacteriology and pathological chemistry and in the obstetric unit before he was [illegible] cal registrar at Westminster Hospital [illegible] l registrar, [illegible] ır working [illegible] Hospital, Boston. On his return h [illegible] unit at U.C.H. During [illegible] as officer in charge of a [illegible] and Italy. Later, with the local rank of brigadier, he was consulting physician to Allied Land Forces in South East Asia. In 1946 he became deputy director of the medical unit at U.C.H., when he was also elected to the staff as assistant physician. In 1935 he introduced, through our columns, the use of mandelic acid in the treatment of urinary infections, and much of his work has been concerned with the urinary tract. He has also written on alimentary dysfunction, including steatorrhœa, and latterly on problems of hypertension. In 1938 he was awarded the Raymond Horton-Smith prize for his M.D. thesis and in 1941 he was elected F.R.C.P.

On May 12, 15, and 22, at University College, Dr. G. B. Wislocki, professor of anatomy at Harvard University, will lecture on the Cytology and Histochemistry of the Uterus and Placenta. On Tuesday, May 23, at St. Mary's Hospital Medical School, Dr. Perrin H. Long, F.R.C.P., professor of preventive medicine at the Johns Hopkins University School of Medicine, will speak on the Use of Antibiotics in the Treatment of Infectious Diseases with special reference to the Effects of 'Aureomycin' and 'Chloramphenicol.' On June 8, at King's College, Dr. L. S. Stone, professor of comparative anatomy at Yale University, will describe the Development of Normal and Abnormal Vision Observed in Animals with Transplanted Eyes. All the lectures will take place at 5.30 P.M.

Dr. F. Bremer, professor of general pathology, University of Brussels, will lecture at University College on May 17, 19, and 23, at 5.15 P.M. on the Physiology of the Central Nervous System.

University of Dublin

On Thursday, May 4, at 4.30 P.M. at the School of Physic, Trinity College, Prof. E. C. Dodds, F.R.S., will deliver the John Mallet Purser lecture. He has chosen as his subject Synthetic Œstrogens in Treatment with special reference to Malignant Disease.

Royal College of Physicians of London

Dr. A. E. Clark-Kennedy will deliver the Croonian lectures at the college, Pall Mall East, S.W.1, on Tuesday and Thursday, May 9 and 11, at 5 P.M. He is to speak on the Patient and his Disease.

Heberden Society

On Friday, June 2, at 5 P.M. and on Saturday, June 3, at 10 A.M., at B.M.A. House, Tavistock Square, London, W.C.1, Prof. Hans Selye of Montreal will give the Heberden oration for 1950 on the Rheumatic Diseases as Diseases of Adaptation.

Conference on Tuberculosis

The Socialist Medical Association is holding a conference at Denison House, Vauxhall Bridge Road, London, S.W.1, on Saturday, April 22. At the afternoon session at 2.15 P.M. on the Shortage of Hospital Beds for Tuberculous Patients, Dr. Horace Joules and Dr. H. J. Trenchard will speak, and at the evening session at 5.30 P.M. on Social Implications of the Breakdown of the Tuberculosis Service Dr. C. K. Cullen will speak.

Editorship of Popular Health Journal

Dr. I. Harvey Flack, who is at present assistant editor of the *British Medical Journal*, has been appointed editor of the British Medical Association's new popular health journal.

Secretaryship of B.M.A.

The British Medical Association has granted to its secretary, Dr. Charles Hill, M.P. for Luton, "such leave of absence as is necessary for the full and efficient performance of his Parliamentary duties." In his absence, Dr. Angus Macrae, one of the deputy secretaries, will act in his stead.

Royal College of Surgeons of England

At a meeting of the council on April 13, with Sir Cecil Wakeley, the president, in the chair, Jacksonian prizes for 1949 were awarded to F. Masina, F.R.C.S., and F. G. Hollands, M.R.C.S., for their essays on Malignant Disease of the Urinary Bladder. The subject for essays in 1951 will be Neoplasm, Innocent and Malignant, of the Pancreas.

Mr. R. S. Corbett and Mr. N. C. Lake were elected members of the court of examiners. Dr. Walter Briggs, Dr. Leonard Colebrook, Dr. Cuthbert Dukes, and Dr. A. B. Beresford-Jones were elected to the fellowship without examination as medical practitioners of at least 20 years' standing. Dr. Arthur W. Allen, chairman of the board of regents of the American College of Surgeons, was elected a Hunterian professor for 1950. Prof. A. B. P. Amies of Melbourne was appointed Charles Tomes lecturer on the recommendation of the Faculty of Dental Surgery.

A Leverhulme scholarship was awarded to Mr. D. I. Williams, F.R.C.S., for his research on congenital hydroureter in childhood. Dr. H. D. Ross was appointed Bland-Sutton scholar.

The following diplomas were granted jointly with the Royal College of Physicians:

D.L.O.—Stanislaw Arcizewski.

D. Phys. Med.—T. K. Davidson, K. A. Sowden, H. T. van Diggelen, E. F. C. Wadge.

D.T.M. & H.—Adegboyega Folaranmi Adedoyin, Amirah [illegible] endar Paul Bector, Harry Binysh, Robert [illegible] abhji Doshi, Alexander Douglas, Simeon [illegible] M. T. Gillies, W. H. Grant, Jayaratnam [illegible] zzul Husain, J. A. Hyde, S. W. Hynd, Pet [illegible] Balawant Mahadeo Kher, P. H. Lomax, [illegible] erzy Marek Nowakowski, Hassan Omer, [illegible] arlos Sanmartin-Barberi, Yahia Aly Shaheen, Betty E. Shortland, Bin Mohamed Attas Salaiman, E. J. Talbott, Edith M. Waterhouse, J. W. Weston.

D.O.M. & S.—Mahmood Ali, Mohammad Husain Alvi, Bamandas Bandyopadhyay, D. G. Bisset, John Burns-Brown, P. T. Clover, Le R. C. Cody, Alvin Cohen, Timothy Daly, J. B. Dancer, Than Dok, Catherine M. Fitzpatrick, H. G. Frampton, John Gloster, E. C. Glover, Indu Bhushan Goel, E. J. Hanley, S. A. Heath, Enid A. Hughes, J. B. Hutten, H. B. Jacobs, Annie M. Jones, Iris Kane, Sunawar Ali Lashkor, David Lyen, H. M. Lyons, F. D. McAuley, Margeret E. McClelland, C. [illegible] ar, J. M. D. Meyer, Shree Mohan Mishr [illegible] stry, E. L. Moore, N. S. Moores, K. S. [illegible] J. C. Parr, James Pendergast, T. B. Rankin[illegible] G. J. Romanes, Amal Kumar Sen, Mossa Hu[illegible] Dip Sinha, J. J. Teeuwen, R. S. Thubron, [illegible] D. J. K. Wilkie.

D.O.—T. H. Bassett, Agnes M. Brogan, G. C. T. Burfitt-Williams, F. J. Curtis, D. W. Ellis-Jones, Elizabeth M. M. Fisher, Anant Mahadeo Gokhale, J. L. Kyle, Dalachant Harripersad Sinanan, R. J. H. Smith.

The Physical Basis of Mind

The Third Programme series of talks on this subject is to be repeated, starting on April 17, for those who could not hear the talks last year or who may wish to hear them again. Sir Henry Dale, O.M., F.R.S., in introducing the series, will pay a tribute to Sir Charles Sherrington, now well over 90 years of age, and Prof. E. D. Adrian, O.M., F.R.S., will follow with a talk, on What Happens When We Think. In the second talk, on April 19, Prof. W. E. Le Gros Clark, F.R.S., will discuss the Anatomical Background of Mental Processes, and on April 25, Prof. S. Zuckerman, F.R.S., will speak on Self-organisation. On April 28 and May 4 two physicians will discuss Consciousness and Speed and Thought. On May 6 Prof. Wilder Penfield, F.R.S., will talk about Evidence from Brain Operations, and Lord Samuel, Prof. A. J. Ayer, and Prof. Gilbert Ryle will join in a philosopher's symposium. The series is to be published in book form later.

his Ingleby lecture in 1907, and on the operative treatment of malignant disease of the uterus was early and important.

A colleague writes: "Doctor Thomas Wilson, as he was called by generations of Birmingham people, began his professional life in 1878, when medicine was almost entirely a clinical art and surgeons still spoke of laudable pus. The natural sciences had barely developed beyond the state of providing hobbies for enthusiastic amateurs. The lives of ordinary folk had not changed greatly during several centuries. He lived to behold and to read of marvels and of horrors in science and in the actions of nations of which those of his own contemporaries who lived only to the allotted span of three score and ten would not have dreamed. He did not dwell in the past but at each moment of his life he acted with a keen and balanced attention to the present. He was a sound and careful surgeon whose technique, though deliberate, produced results of a uniformly high quality; many will recall his association with his surgical colleague, Sir Gilbert Barling, in their nursing-home in Cornwall Street, and it may be remarked that in his hands the Pfannenstiel transverse incision for opening the lower abdomen yielded excellent results—incisional hernias did not occur and hæmatoma of the abdominal wall, the chief fault of the method, was rare.

"Sturdy in appearance and in character, Wilson will live long in the memories of those who knew him; for his common sense and his cheerful and frank manner left an abiding impression of kindliness, of sincerity, and of a personality which was direct in work and action. Brought up in days when professional people had little leisure or liking for games or hobbies, nevertheless he was a skilful and enthusiastic gardener and in later years he enjoyed field geology."

He retired in 1927 and with his wife, formerly Miss Loxton of Cannock, who died in 1947, he settled happily among the Malvern Hills. They had no children.

Diary of the Week

APRIL 23 TO 29

Monday, 24th

INSTITUTE OF LARYNGOLOGY AND OTOLOGY, 330, Gray's Inn Road, W.C.1
9.30 A.M. Mr. F. C. W. CAPPS: Tumours of the Postnasal Space.
MEDICAL SOCIETY OF LONDON, 11, Chandos Street, W.1
8.30 P.M. Mr. N. R. Barrett, Mr. R. H. Franklin: Non-malignant Affections of the Œsophagus.

Tuesday, 25th

UNIVERSITY OF LONDON
5 P.M. (Guy's Hospital Medical School, S.E.1.) Prof. G. Westin (Stockholm): Histological Aspects of Gingival Disease.

Wednesday, 26th

INSTITUTE OF PSYCHIATRY, Maudsley Hospital, Denmark Hill, S.E.5
4.30 P.M. Dr. E. Stengel: Psychiatry lecture-demonstration.
HARVEIAN SOCIETY OF LONDON
8.15 P.M. (26, Portland Place, W.1.) Dr. H. R. Vickers: The Dermatitis-eczema Problem as a Guide to Future Trends in Medicine.

Thursday, 27th

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL, S.W.1
4.30 P.M. Dr. Anthony Feiling: Neurology demonstration.
MEDICO-LEGAL SOCIETY
8.15 P.M. (*26, Portland Place, W.1.*) *Dr. F. E. Camps*: Carbon Monoxide Poisoning—Suicide, Accident, and Murder.
HONYMAN GILLESPIE LECTURE
5 P.M. (University New Buildings, Teviot Place, Edinburgh.) Prof. R. C. Walmsley: Comparative Anatomy of the Heart.

Friday, 28th

ROYAL COLLEGE OF OBSTETRICIANS AND GYNÆCOLOGISTS, 58, Queen Anne Street, W.1
NOON Dr. A. M. Sutherland: Functional Uterine Hæmorrhage.
3 P.M. Mr. Bryan Jeaffreson: Management of the Occipito-posterior Position.
5 P.M. Prof. Hilda Lloyd, Mr. Jeaffreson, Mr. Charles Read, Dr. David Shaw, Dr. A. J. Wrigley: Any Questions?
EMPIRE RHEUMATISM COUNCIL
4.30 P.M. (Apothecaries' Hall, Blackfriars Lane, E.C.4.) Sir Adolphe Abrahams: Differential Diagnosis of Rheumatism. (First lecture of a weekend postgraduate course.)
MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES, 11, Chandos Street, W.1
8 P.M. Dr. C. S. Nicol: Cardiovascular Syphilis.

Saturday, 29th

ROYAL COLLEGE OF OBSTETRICIANS AND GYNÆCOLOGISTS
9.45 A.M. Mr. H. I. McClure: Heart-disease in Pregnancy.
11.30 A.M. Mr. A. Briant Evans: Operative Treatment of Advanced Carcinoma of the Cervix.

Notes and News

PUBLIC HEALTH LABORATORY SERVICE

SINCE the Public Health Laboratory Service was placed on a permanent basis after the war, the Medical Research Council have continued to administer it as agents for the Ministry of Health. It has been decided that the council will, with certain reservations on matters of broad policy, now delegate this function to a Public Health Laboratory Service Board, composed in the first instance as follows: Mr. A. Landsborough Thomson, D.SC. (chairman), Prof. S. P. Bedson, F.R.S., Dr. C. Metcalfe Brown, Dr. A. N. Drury, F.R.S., Sir Percival Hartley, F.R.S., Sir Wilson Jameson (ex officio), and Dr. A. A. Miles, with Dr. W. H. Bradley as observer from the Ministry of Health.

The Emergency Public Health Laboratory Service in England and Wales was organised by the Medical Research Council before the war, at the request of the Government, and was brought into being in 1939. Statutory authority for continuing it on a permanent basis was given by section 17 of the National Health Service Act, 1946. The director of the service is Prof. G. S. Wilson.

THE MEDICAL DIRECTORY

THE contents of the 1950 issue[1] have been thoroughly reshuffled. As regards the general alphabetical lists, part 1 contains London, Scotland, Wales, Ireland, Abroad, and Services—in that order, gallant little Wales having been "demoted"—and part 2 contains the English Provinces. Each geographical section has had its universities, colleges, hospitals, schools of medicine, various other institutions, and medical officers of health relegated to the after end of part 2, where they are arranged in a different order from that obtaining in the general alphabetical lists—London, English Provinces and Wales, Scotland, Northern Ireland, and Eire. The hospitals are arranged according to the new areas. The disclaimed hospitals and independent organisations are listed separately. The convalescent institutions, regional hospital boards, and local medical committees seem to have disappeared. The medical practitioners listed number 77,730 against the 74,523 of last year, and last year's "foreign list" of 864 names has been dropped.

CARE OF THE ELDERLY

AT a meeting of the Medical Society for the Care of the Elderly, in London on Feb. 3, the employment of elderly persons in industry was discussed by Dr. G. P. Keatinge. He pointed out that it is impracticable to employ elderly men on jobs usually done by boys or young people, and that many old workmen prefer to go on with what would seem to be unsuitable jobs. Old people are anxious to continue work as long as possible; but it is impracticable to reduce their working hours, since they feel that this makes more conspicuous their lessening powers.

DESCRIPTION OF JUNIOR HOSPITAL POSTS

FOR the purpose of recruitment to the Forces the Central Medical War Committee classifies house-officer and registrar posts into A, B2, or B1. Hospital authorities therefore use this terminology in advertisements to describe vacant posts. In a circular to such authorities the Ministry of Health says that the Central Medical War Committee has been consulted about the practicability of using the terminology used in the Terms and Conditions of Service of Hospital Medical Staff for all purposes, including the recruitment of doctors to the Forces; and the committee raises no objection. For the time being, however, a dual terminology is to be used. Accordingly, hospital authorities are asked during the next few months to use the following dual description both in advertisements and in correspondence regarding the recruitment of medical staff:

House-officer posts.—House-officer, first post [A] (second or third post [B2], as the case may be); or house-physician (or house-surgeon, &c.), salary £350 [A], £400 or £450 [B2], a year, according to experience.

Registrar posts.—Junior registrar [B1]; registrar [B1]; senior registrar [B1].

Junior hospital medical officer.—[B1].

When the new terminology has become familiar to all concerned with the appointment and recruitment of junior hospital staff the old classification of posts as A, B2, and B1 will be discontinued; and it is hoped that this stage can be reached by Sept. 30.

---

[1] London: J. & A. Churchill. 1950. Pp. 2676. £3 3s.

University of London

Dr. M. L. Rosenheim has been appointed to the chair of medicine at University College Hospital Medical School.

Dr. Rosenheim, who is 42 years of age, was educated at Shrewsbury School and St. John's College, Cambridge, where, in 1929, he took a first-class in part I of the natural sciences tripos and was elected to a foundation scholarship. At University College Hospital he held Goldsmid and Filliter exhibitions and he was awarded the Fellows and Tuke medals. After taking his B.CHIR. in 1932, he held house-appointments at U.C.H., and spent a year in research in the departments of bacteriology and pathological chemistry and in the obstetric unit before he was appointed assistant medical registrar at Westminster Hospital in 1934. Two years later he returned to U.C.H. as medical registrar, and in 1939, with a Bilton Pollard fellowship, he spent a year working under Dr. Fuller Albright at the Massachusetts General Hospital, Boston. On his return he was appointed first assistant in the medical unit at U.C.H. *During the late war he served with the R.A.M.C.* as officer in charge of a medical division in Palestine, Sicily, Algiers, and Italy. Later, with the local rank of brigadier, he was consulting physician to Allied Land Forces in South East Asia. In 1946 he became deputy director of the medical unit at U.C.H., when he was also elected to the staff as assistant physician. In 1935 he introduced, through our columns, the use of mandelic acid in the treatment of urinary infections, and much of his work has been concerned with the urinary tract. He has also written on alimentary dysfunction, including steatorrhœa, and latterly on problems of hypertension. In 1938 he was awarded the Raymond Horton-Smith prize for his M.D. thesis and in 1941 he was elected F.R.C.P.

On May 12, 15, and 22, at University College, Dr. G. B. Wislocki, professor of anatomy at Harvard University, will lecture on the Cytology and Histochemistry of the Uterus and Placenta. On Tuesday, May 23, at St. Mary's Hospital Medical School, Dr. Perrin H. Long, F.R.C.P., professor of preventive medicine at the Johns Hopkins University School of Medicine, will speak on the Use of Antibiotics in the Treatment of Infectious Diseases with special reference to the Effects of 'Aureomycin' and 'Chloramphenicol.' On June 8, at King's College, Dr. L. S. Stone, professor of comparative anatomy at Yale University, will describe the Development of Normal and Abnormal Vision Observed in Animals with Transplanted Eyes. All the lectures will take place at 5.30 P.M.

Dr. F. Bremer, professor of general pathology, University of Brussels, will lecture at University College on May 17, 19, and 23, at 5.15 P.M. on the Physiology of the Central Nervous System.

University of Dublin

On Thursday, May 4, at 4.30 P.M. at the School of Physic, Trinity College, Prof. E. C. Dodds, F.R.S., will deliver the John Mallet Purser lecture. He has chosen as his subject Synthetic Œstrogens in Treatment with special reference to Malignant Disease.

Royal College of Physicians of London

Dr. A. E. Clark-Kennedy will deliver the Croonian lectures at the college, Pall Mall East, S.W.1, on Tuesday and Thursday, May 9 and 11, at 5 P.M. He is to speak on the Patient and his Disease.

Heberden Society

On Friday, June 2, at 5 P.M. and on Saturday, June 3, at 10 A.M., at B.M.A. House, Tavistock Square, London, W.C.1, Prof. Hans Selye of Montreal will give the Heberden oration for 1950 on the Rheumatic Diseases as Diseases of Adaptation.

Conference on Tuberculosis

The Socialist Medical Association is holding a conference at Denison House, Vauxhall Bridge Road, London, S.W.1, on Saturday, April 22. At the afternoon session at 2.15 P.M. on the Shortage of Hospital Beds for Tuberculous Patients, Dr. Horace Joules and Dr. H. J. Trenchard will speak, and at the evening session at 5.30 P.M. on Social Implications of the Breakdown of the Tuberculosis Service Dr. C. K. Cullen will speak.

Editorship of Popular Health Journal

Dr. I. Harvey Flack, who is at present assistant editor of the *British Medical Journal*, has been appointed editor of the British Medical Association's new popular health journal.

Secretaryship of B.M.A.

The British Medical Association has granted to its secretary, Dr. Charles Hill, M.P. for Luton, "such leave of absence as is necessary for the full and efficient performance of his Parliamentary duties." In his absence, Dr. Angus Macrae, one of the deputy secretaries, will act in his stead.

Royal College of Surgeons of England

At a meeting of the council on April 13, with Sir Cecil Wakeley, the president, in the chair, Jacksonian prizes for 1949 were awarded to F. Masina, F.R.C.S., and F. G. Hollands, M.R.C.S., for their essays on Malignant Disease of the Urinary Bladder. The subject for essays in 1951 will be Neoplasm, Innocent and Malignant, of the Pancreas.

Mr. R. S. Corbett and Mr. N. C. Lake were elected members of the court of examiners. Dr. Walter Briggs, Dr. Leonard Colebrook, Dr. Cuthbert Dukes, and Dr. A. B. Beresford-Jones were elected to the fellowship without examination as medical practitioners of at least 20 years' standing. Dr. Arthur W. Allen, chairman of the board of regents of the American College of Surgeons, was elected a Hunterian professor for 1950. Prof. A. B. P. Amies of Melbourne was appointed Charles Tomes lecturer on the recommendation of the Faculty of Dental Surgery.

A Leverhulme scholarship was awarded to Mr. D. I. Williams, F.R.C.S., for his research on congenital hydro-ureter in childhood. Dr. H. D. Ross was appointed Bland-Sutton scholar.

The following diplomas were granted jointly with the Royal College of Physicians:

D.L.O.—Stanislaw Arcizewski.

D. Phys. Med.—T. K. Davidson, K. A. Sowden, H. T. van Diggelen, E. F. C. Wadge.

D.T.M. & H.—Adegboyega Folaranmi Adedoyin, Amirali Abdulkarim Alidina, Narendar Paul Bector, Harry Binysh, Robert Bradley, Dhirubhai Vallabhji Doshi, Alexander Douglas, Simeon Fernando, H. B. Gibson, M. T. Gillies, W. H. Grant, Jayaratnam Gulasekharam, C. W. J. Hingston, Tafazzul Husain, J. A. Hyde, S. W. Hynd, Peter Jordan, Ahmad Kabir, Balawant Mahadeo Kher, P. H. Lomax, Behman Sorab Moos, Jerzy Marek Nowakowski, Hassan Omer, George Ou Ta Wei, Carlos Sanmartin-Barberi, Yahia Aly Shaheen, Betty E. Shortland, Bin Mohamed Attas Sulaiman, E. J. Talbott, Edith M. Waterhouse, J. W. Weston.

D.O.M. & S.—Mahmood Ali, Mohammad Husain Alvi, Bamandas Bandyopadhyay, D. G. Bisset, John Burns-Brown, P. T. Clover, Le R. C. Cody, Alvin Cohen, Timothy Daly, J. B. Dancer, Than Dok, Catherine M. Fitzpatrick, H. G. Frampton, John Gloster, E. C. Glover, Indu Bhushan Goel, E. J. Hanley, S. A. Heath, Enid A. Hughes, J. B. Hutten, H. B. Jacobs, Annie M. Jones, Iris Kane, Sunawar Ali Lashkor, David Lyen, H. M. Lyons, F. D. McAuley, Margeret E. McClelland, C. M. McLean, Mohamed Mazhar, J. M. D. Meyer, Shree Mohan Mishra, Khurshed Bomanji Mistry, E. L. Moore, N. S. Moores, K. S. Murray, Mungo Park Ross, J. C. Parr, James Pendergast, T. B. Rankin[illegible], [illegible], G. J. Romanes, Amal Kumar Sen, Mossa Hussa[illegible] [illegible] Dip Sinha, J. J. Teenwen, R. S. Thubron, [illegible], [illegible], D. J. K. Wilkie.

D.O.—T. H. Bassett, Agnes M. Brogan, G. C. T. Burfitt-Williams, F. J. Curtis, D. W. Ellis-Jones, Elizabeth M. M. Fisher, Anant Mahadeo Gokhale, J. L. Kyle, Dalachant Harripersad Sinanan, R. J. H. Smith.

D.C.H.—W. F. Allan, N. G. Anderson, Amiya Kumar Basu, Kathleen N. Berger, T. B. Binns, Dorothy J. Blake, Mary M. M. Boyd, R. St. J. Buxton, I. J. Carré, Patricia J. Chapman, Phyllis M. E. Cook, Anne L. Craig, Evelyn M. Crawford, B. A. D. Gurtin, A. R. Darlow, Errington Ellis, Harriet E. Faris, A. W. Ferguson, Margaret J. W. Finlayson, D. M. Flanagan, Mary E. Forrester, Margeret F. Notes and News

PUBLIC HEALTH LABORATORY SERVICE

SINCE the Public Health Laboratory Service was plac on a permanent basis after the war, the Medical Rese Council have continued to administer it as agents for t Ministry of Health. It has been decided that the counc will, with certain reservations on matters of broad polic now delegate this function to a Public Health Laborato Service Board, composed in the first instance as follows Mr. A. Landsborough Thomson, D.SC. (chairman), Prof. S. P Bedson, F.R.S., Dr. C. Metcalfe Brown, Dr. A. N. Drury F.R.S., Sir Percival Hartley, F.R.S., Sir Wilson Jameson (e officio), and Dr. A. A. Miles, with Dr. W. H. Bradley as observer from the Ministry of Health.

The Emergency Public Health Laboratory Service in England and Wales was organised by the Medical Research Council before the war, at the request of the Government, and was brought into being in 1939. Statutory authority for continuing it on a permanent basis was given by section 17 of the National Health Service Act, 1946. The director of the service is Prof. G. S. Wilson.

THE MEDICAL DIRECTORY

THE contents of the 1950 issue[1] have been thoroughly reshuffled. As regards the general alphabetical lists, part 1 contains London, Scotland, Wales, Ireland, Abroad, and Services—in that order, gallant little Wales having been "demoted"—and part 2 contains the English Provinces. Each geographical section has had its universities, colleges, hospitals, schools of medicine, various other institutions, and medical officers of health relegated to the after end of part 2, where they are arranged in a different order from that obtaining in the general alphabetical lists—London, English Provinces and Wales, Scotland, Northern Ireland, and Eire. The hospitals are arranged according to the new areas. The disclaimed hospitals and independent organisations are listed separately. The convalescent institutions, regional hospital boards, and local medical committees seem to have disappeared. The medical practitioners listed number 77,730 against the 74,523 of last year, and last year's "foreign list" of 864 names has been dropped.

CARE OF THE ELDERLY

AT a meeting of the Medical Society for the Care of the Elderly, in London on Feb. 3, the employment of elderly persons in industry was discussed by Dr. G. P. Keatinge. He pointed out that it is impracticable to employ elderly men on jobs usually done by boys or young people, and that many old workmen prefer to go on with what would seem to be unsuitable jobs. Old people are anxious to continue work as long as possible; but it is impracticable to reduce their working hours, since they feel that this makes more conspicuous their lessening powers.

DESCRIPTION OF JUNIOR HOSPITAL POSTS

FOR the purpose of recruitment to the Forces the Central Medical War Committee classifies house-officer and registrar posts into A, B2, or B1. Hospital authorities therefore use this terminology in advertisements to describe vacant posts. In a circular to such authorities the Ministry of Health says that the Central Medical War Committee has been consulted about the practicability of using the terminology used in the *Terms and Conditions of Service of Hospital Medical Staff* for all purposes, including the recruitment of doctors to the Forces; and the committee raises no objection. For the time being, however, a dual terminology is to be used. Accordingly, hospital authorities are asked during the next few months to use the following dual description both in advertisements and in correspondence regarding the recruitment of medical staff:

House-officer posts.—House-officer, first post [A] (second or third post [B2], as the case may be); or house-physician (or house-surgeon, &c.), salary £350 [A], £400 or £450 [B2], a year, according to experience.

Registrar posts.—Junior registrar [B1]; registrar [B1]; senior registrar [B1].

Junior hospital medical officer.—[B1].

When the new terminology has become familiar to all concerned with the appointment and recruitment of junior hospital staff the old classification of posts as A, B2, and B1 will be discontinued; and it is hoped that this stage can be reached by Sept. 30.

SOME LIMITATIONS OF PSYCHIATRY*

F. P. HALDANE
M.B. Glasg., D.P.M.
PSYCHIATRIST TO THE WEST MIDDLESEX HOSPITAL

THE expectations with which cases of psychoneurosis are referred to the psychiatrist have often seemed to me to be a little unrealistic. In the hope of approaching a more balanced view of the therapeutic possibilities, I shall first deal briefly with two factors which seem liable to distort one's judgment of the matter, and shall then try to show where, in my opinion, the real problem lies.

ATTITUDE TO PSYCHOTHERAPY

Psychiatry means "mind-healing," and from this we derive not only the treatment *of* mind, which includes, for example, such procedures as the arrest of luetic processes in the brain, but also treatment *by* mind, which is what we principally use in dealing with psychoneurosis.

Now treatment by mind must largely mean treatment by thoughts and their emotional accompaniments, and as such can only be applied through the use of words as a vehicle. Can such a mode of treatment escape comparison with the ancient practices of sorcery, spells, incantations, faith-healing, and miraculous cures? Of course it cannot, and the consequences of this connection cannot be completely avoided. We adults have consciously outgrown our infantile beliefs in the omnipotence of thoughts and words; but these beliefs still stir from time to time in the less self-conscious regions of our minds, influencing our conscious judgments, now tempting us to credulity, now calling forth contemptuous repudiation. Such a state of affairs is bound to influence our attitude to the psychiatrist, who stands inevitably and almost by definition associated with ideas of magic. Thus he appears now as a useless charlatan, now as one possessed of some mysterious power, in virtue of which a few talks with him may cure a severe neurosis. I do not suggest that such opinions are commonly consciously avowed, but only that a latent tendency in this direction often exists and plays its ambiguous part in distorting the opinions we may form when we are deciding what we may expect a psychiatrist to do for one or other of our patients. There is not a great deal that one can do about this, but a partial awareness of the tendency may to some small extent reduce its effects.

APPROACH TO ILLNESS

There is a second and more accessible source of error in the expectations that may be formed of what a psychiatrist should be able to do for a particular patient, and of how long he should take to do it. I refer to your clinical experience with your own medical, surgical, and obstetrical patients.

I know, of course, that nowadays increasing stress is laid upon treating the patient as a whole organism and even as a whole human being. I know, too, that all progressive physicians, and many surgeons also, pay lip-service to this ideal. But in practice, and particularly in one's ætiological and pathological assessments, I doubt if one is often successful, in face of one's raw clinical experience, in avoiding slipping into the attitude that the patient's condition is essentially due to a defect or disorder of this or that or the other bodily organ or system. This patient is ill because of occlusion of a coronary artery, that one because of the formation of stones in the gall-bladder, a third because of changes in the tissues around the joints and so on.

And after all, from an immediately practical point of view, why not? Einstein has no doubt helped the physicists to get a little closer to the truth of the matters in which they are engaged, but there are still many little practical occasions when Euclid is all we need. Certainly this approach may involve us in producing immensely expensive adrenocortical extracts for the relief of rheumatoid sufferers, that *might* be produced much more cheaply and efficiently by the patient himself were he free from chronic emotional stress; but, even should this turn out to be so, an indispensable job of research will have been done. At all events, the actual conditions of our work are such that, for practical purposes, we often have to regard the patient's illness as due to some accidental noxious influence on one or more of his organs or systems, and if we are able to remove or neutralise or arrest this noxious influence or its results we can often count upon a reasonable therapeutic success without ever attempting any interference with the patient on the level of his individual human personality.

The approach to illness that I have discussed as reasonably practical in the fields of medicine, surgery, and obstetrics, if applied to psychiatry, leads inevitably to error and to disappointment. Whereas in these fields the study of the patient as an individual personality is an ultimate desideratum, in psychiatry it is a first essential; indeed, for a fuller understanding, it must ultimately be extended to embrace a study of the dynamic laws of the particular human social system of which he forms a part.

When we transfer the more restricted attitude to disease from general medicine to psychiatry, it is liable to give rise to misleading notions, to naïve psychopathologies and inadequate therapies based upon them. We may, for example, think that a patient's symptoms are due to an idea that has entered his mind—let us say the idea that he has cancer. He got this idea because his father died of cancer, and he has recently heard that cancer is hereditary. As a result he has become worried about his health. He has lost his appetite, lost weight, and begun to brood about some obscure minor discomfort, some slight dyspepsia. From this our course seems quite clear: we have to take this idea out of his head and put in a better one as antidote; for example, that he is fortunate in the enjoyment of absolutely first-rate health. This theory is plausible; but our medical theories must be more than plausible; they must also approach the truth, and there is too little truth in this one. Of course, in many cases there may be nothing better that we can do for the patient. Then we must be quite clear that we are simply administering a psychiatric placebo, and we will not require to call in a specialist to administer a placebo, though it may be desirable to obtain his opinion that this is all that is possible.

A less naive approach is based upon the common notion that the neurosis is due to an accidental traumatic experience. The patient has had a bad shock. This shock has gone straight down into his unconscious and has been playing havoc there ever since. Well, we have to probe around until we touch it. We shall know when we do this by the way the patient jumps. Then we have to put the patient into light hypnosis and bring the shock up into his consciousness, where it will explode in tears and terror. The patient, shaken but relieved, will go home and write to the Ministry to stop his pension. This sort of thing may happen often enough in Hollywood, but in ordinary practice it is seldom like that. Now and again, especially in war-time, one has a clinical experience that seems to resemble this just enough to make the theory stick, but as a basis for understanding and treating the psychoneurosis we meet in daily practice it is quite misleading.

---

6609

Medical Bequest

The widow of Sir Humphry Rolleston has left the residue of her £42,000 estate, "as my late husband wished," to the master and fellows of St. John's College, Cambridge, to help medical students at the college.

Joint Consultative Committees

Boards of governors and management committees are being asked by the Ministry of Health to set up joint consultative committees of managements and workers. These committees will consider matters affecting the efficiency of the hospital service and the welfare of staffs, but not wages and hours.

West London Medico-Chirurgical Society

On Monday, May 15, at 8.30 P.M., at 1, Wimpole Street, W.1, Admiral Lord Mountevans will deliver the Cavendish lecture on Antarctic Exploration. The annual banquet will be held on Friday, June 2, at the Royal College of Surgeons. Further information may be had from the hon. secretaries, Mr. J. R. C. Hindenach, 81, Harley Street, W.1, and Dr. D. Hector-Jones, D.M.R.D., West London Hospital, W.6.

Guernsey and U.C.H.

University College Hospital, London, has arranged with the Guernsey States Board of Health to send a limited number of its tuberculous patients to the King Edward Hospital Sanatorium in Guernsey. This hospitality is offered in return for the thoracic surgery which has been performed since the start of National Health Service at the hospital on patients from Guernsey without cost to the island authority.

Births, Marriages, and Deaths

BIRTHS

AYLETT.—On April 12, in London, the wife of Mr. Stanley Aylett, F.R.C.S.—a son.

BROADHEAD.—On April 9, the wife of Dr. D. L. Broadhead—a son.

DICKSON.—On April 14, the wife of Dr. A. M. Dickson—a son.

ELMHIRST.—On April 9, in London, the wife of Mr. Edward Elmhirst, F.R.C.S.—a daughter.

HAWES.—On March 29, at Ewhurst, the wife of Dr. E. I. B. Hawes —a son.

HAYES.—On April 8, at Woking, the wife of Dr. Stuart Hayes —a son.

HELM.—On April 11, at Devonport, the wife of Dr. Cyril Helm —a daughter.

HUGGILL.—On April 11, in London, the wife of Mr. P. H. Huggill, F.R.C.S.—a son.

MACKINNON.—On April 3, the wife of Dr. Donald Mackinnon —a daughter.

METCALFE.—On April 8, in London, the wife of Dr. J. B. Metcalfe —a daughter.

NELLEN.—On April 12, in Cape Town, the wife of Dr. Maurice Nellen—a son.

NEVIN.—On April 5, in London, the wife of Mr. R. W. Nevin, F.R.C.S.—a son.

OLDHAM.—On April 13, at Shrewsbury, the wife of Dr. J. S. Oldham —a daughter.

ORFORD SMITH.—*On April 11, in Birmingham, the wife of Dr.* E. S. Orford Smith—a daughter.

ROBERTSON.—On April 12, in Salisbury, Southern Rhodesia, the *wife of Dr. John Robertson—a son.*

SMITH.—On April 3, at Oxford, the wife of Dr. F. H. N. Smith —a son.

STODDART.—On April 10, in London, the wife of Dr. I. W. Stoddart —a son.

SYKES.—On April 5, at Newcastle upon Tyne, the wife of Dr. R. G. Sykes—a daughter.

THOMSON.—On April 10, at Hereford, the wife of Dr. R. T. Thomson —a daughter.

TOBER.—On April 6, at Reigate, the wife of Dr. Archibald Tober —a son.

MARRIAGES

ALTMANN—CROWDER.—On March 25, at East Molesey, Surrey, Rolf Altmann, M.D., to Helen Evelyn Crowder.

PERROTT—HODGSON.—On March 30, at Darlington, John William Perrott, M.R.C.S., to Nancy Hodgson, S.R.N., S.C.M.

DEATHS

CARSLAW.—On April 14, in Glasgow, James Carslaw, M.A., M.B. Glasg.

FEAVER.—On April 6, at Hove, Lewis Feaver, M.R.C.S., aged 79.

GILMORE.—On April 10, in London, Owen Gilmore, M.D. Brux., F.R.C.S.E., aged 87.

GREEN.—On April 10, at Guildford, Charles Robert Mortimer Green, M.D. Durh., F.R.C.S., D.P.H., colonel, I.M.S., retd, aged 86.

JENNINGS.—On April 3, at Bath, Arthur Richard Jennings, M.A., M.B. Camb., D.T.M.

MAURICE.—On March 8, at Marlborough, George Thelwall Kindersley Maurice, C.M.G., C.B.E., M.R.C.S., aged 83.

NORRINGTON.—On April 11, Henry Lawrence Weekes Norrington, D.S.O., lieut.-colonel, R.A.M.C. retd.

PALMER.—On April 6, at Bournemouth, Francis James Palmer, F.R.C.S.I., lieut.-colonel, R.A.M.C. retd.

SAVAGE.—On March 30, Herbert Nibbs Savage, M.R.C.S., aged 53.

STARLING.—On April 10, at Norwich, Hubert John Starling, M.D. Lond., D.P.H., aged 76.

Lebanon Hospital for Mental Diseases

The 51st annual meeting of this hospital, which is a Asfuriyeh, near Beirut, will be held at Manson House, 26 Portland Place, London, W.1, at 3 P.M. on Friday, April 28 Sir Ronald Storrs will preside and the speakers will includ Dr. Alexander Kennedy, professor of psychological medicin in the University of Durham. The London office of the hospital is at Drayton House, Gordon Street, W.C.1.

Dr. Jessie Macgregor Prize for Medical Women

An award of this prize (£50) will be made in July for the best record of original work in the science of medicine. It is open to women who are graduates in medicine of the University of Edinburgh or who have taken the Scottish triple qualification. Applications must reach the convener of trustees, 9, Queen Street, Edinburgh, 2, not later than June 30.

Dr. J. L. Lovibond is visiting Cyprus on behalf of the British Council to inspect hospitals and to give demonstrations on the use of the cardiograph.

Appointments

BOURDILLON, J. F., B.M. Oxfd, F.R.C.S.: cons. orthopædic surgeon, North Gloucestershire clinical area.

BURN, MATTHEW, M.C., F.R.C.P.E., D.P.H., D.T.M. & H.: M.O.H., *Birmingham.*

COWEN, E. D. H., B.A., M.D. Camb., M.R.C.P.: physician, St. Albans City Hospital and Lister, Chalkdell and North Herts and South Beds hospitals.

DOBNEY, G. H., M.B. Lond., D.PHYS.MED.: physician i.c. physical medicine, Whittington Hospital.

DOUGHTY, A. G., M.B. Lond., D.A.: cons. anæsthetist, Kingston group of hospitals, Surrey.

EVANS, C. C., M.A., M.R.C.S.: consultant in electro-encephalography, Central Middlesex Hospital.

FENTON, ELIZABETH, M.B. Lpool, D.A.: cons. anæsthetist, Cheshire Joint Sanatorium, Market Drayton.

GILLET, J. A., M.B. Lpool, D.P.H.: senior school M.O. and deputy M.O.H., Rotherham.

GORKA, A. M., MED.DIP. Cracow: anæsthetist, Stirling Royal Infirmary.

HARRISON, G. A., B.A., M.D. Camb.: cons. pathologist, Royal West Sussex, St. Richard's, and Graylingwell Hospitals.

HUNTER, R. M. M., M.B., B.SC. Edin., M.R.C.P.E., D.P.H., D.P.M.: cons. psychiatrist, Pastures Hospital, Mickleover.

JACKSON, MARGARET, M.B. Lond., D.OBST.: clinical assistant, obstetric and gynæcological department, Royal Devon and Exeter Hospital.

JACKSON, THOMAS, F.R.F.P.S.: dental surgeon, North Gloucestershire clinical area.

LANGLEY, D. A., F.R.C.S., D.O.M.S.: ophthalmic surgeon, Hounslow Hospital.

MACPHAIL, D. S., M.B., B.SC. St. And., D.P.M.: psychotherapist, St. Bernard's Hospital, Southall, Middx.

MALCOLM, MARION, M.B., B.SC.: asst. pathologist and bacteriologist, Stobhill Hospital, Glasgow.

MILNE, JAMES, M.B., B.SC. Glasg., D.P.M.: physician-superintendent, Hawkhead Mental Hospital, Glasgow.

PALSER, J. E. J., M.R.C.S.: asst. school M.O., Blackpool.

PRETOR [illegible]: asst. M.O., maternity and [illegible]

ROBINSO [illegible] L.C.P.I., D.P.M.: medical supe [illegible] Belfast.

SPENCE-SALES, DOROTHY, M.B. N.Z., D.A.: cons. anæsthetist, *Kingston group of hospitals, Surrey.*

STRINGER, P. R., M.B. Lond., F.R.C.S.: cons. surgeon, St. Albans City Hospital.

TATTERSALL, R. N., O.B.E., M.D. Lond., M.R.C.P.: asst. physician, United Leeds Hospitals.

WHITTLE, C. H., M.A., M.D. Camb., F.R.C.P.: cons. dermatologist, Bedford County Hospital and St. Peter's Hospital.

WOLFE, H. R. I., M.S. Lond., F.R.C.S.: cons. surgeon, National Temperance Hospital.

WRIDE, FANNY, M.B. Lond., D.P.M., D.C.H.: cons. psychiatrist, child-guidance clinic, West End Hospital for Nervous Diseases.

Colonial Service:

BAIRD, D. A., M.B., B.SC. Edin.: director of medical services, Somaliland Protectorate.

BERRIE, J. R. H., M.B. Glasg.: M.O., Nigeria.

CHALMERS, ISABELLA, M.B. Lond.: lady M.O., Federation of Malaya.

CHILTON, NOEL, B.A., D.M. Oxfd, D.T.M. & H.: regional asst. director of medical services, Tanganyika.

CLAPHAM, L. J., M.B. Lond., D.T.M. & H.: deputy director, medical and health services, Sarawak.

COCHEMÉ, M. A. X., B.A., M.B. Camb., D.P.M., D.T.M. & H.: superscale grade-B specialist officer, Federation of Malaya.

EVANS, W. J. M., M.B. Lond., D.P.H.: regional asst. director of medical services, Tanganyika.

HOPKIN, D. A. B., M.B. Lond., D.T.M. & H.: superscale grade-B specialist officer, Federation of Malaya.

HUGHES, W. G. J., B.A. Oxfd, M.R.C.S.: M.O., Zanzibar.

KEEVILL, A. J., M.B.E., M.B. Brist., D.T.M. & H.: regional asst. director of medical services, Tanganyika.

MICHIE, CHARLES, M.B. Aberd., D.T.M. & H.: M.O., Tanganyika.

REIDY, J., M.B., D.P.H.: M.O., Kenya.

SPICER, J. R. C., M.B. Lond., D.T.M. & H.: regional asst. director of medical services, Tanganyika.

SPRINGETT, V. G., F.R.C.S.E.: surgeon specialist, Nigeria.

She enters my office with a brightly smiling face and a sort of challengingly semi-flirtatious manner. She is rather tense, and eyes me keenly as a fencer might his adversary, ready to parry an awaited thrust, determined not to be caught off her guard. I invite her to tell me about herself, but this does not suit her. She tries to make me ask the questions. It has to be a sort of contest, in which I should try to find out what I can about her, a sort of "twenty questions" game. But I point out to her the defensive nature of this attitude, and tell her this is not the best way to set about our business, and I urge her just to tell me, if she can, what troubles her. She then begins, "My husband told me to ask you if I should stop reading books about psychoanalysis and psychology." Thus she again avoids the initiative. I point this out to her and suggest that she must have some reason of her own for coming to see me. She then says that she has come because the doctors have assured her that there is "nothing whatever organically wrong" with her, and that her pains are entirely due to emotional disturbances. As she has been unable to track down the cause of these for herself, and "as the doctors must understand such matters better" than she, she has come for help. I point out to her that there appears to be a discrepancy here; her medical records show that a duodenal ulcer has been present and has been demonstrated radiologically; therefore it is unlikely that the doctors have said there is nothing whatever organically wrong. She agrees that this is so, that she has exaggerated, and I point out the tendency to try to score a debating point by extending her opponent's premise, and so to set a trap for later use. This elicits a somewhat abashed and deprecatory laugh. With some difficulty I manage to lead the conversation around over various relevant topics, but the atmosphere is never really easy. All the time there is the underlying feeling that one is engaged in a sort of verbal sparring or fencing match.

While talking of her psychological reading, she had used the phrase "amateur psychoanalysis." When we later returned to the topic she tried to develop the argument that her interest in such literature was merely a part of her wide interest in books. She had many literary interests and this was just one of them. When I said, "But you call this amateur psychoanalysis," she thought that I was referring not to her book reading but to our interview, and hastened to assure me that I had misunderstood her meaning. Throughout the interview she was hypocritically respectful, in such a way that the irony was almost directly apparent. She asked to be placed on our waiting-list for treatment, and departed, still wearing her brightly smiling mask.

III

If my first case has given you some hint of the basic importance of personality, its intimate connection with neurotic suffering, and the long course of its development, beginning in childhood and serving as a protection from the particular stresses then encountered, I hope that the second will have given you an impression of how carefully a patient strives to preserve this personality inviolate from exploration. My third is intended to develop this point a little further by illustrating how blind a patient may be to his own attitudes, or behaviour, and how he can maintain this blindness in the face of repeated demonstrations.

The patient is a married man of 44, who was originally referred to the surgical specialist on account of pain in the site of an old hernia repair operation, carried out 20 years previously.

I shall omit most of his history and symptoms for my present purpose is only to describe to you some of his behaviour during interviews. There are a few points however that may make his attitude a little more understandable. He was brought up in a strict patriarchal type of family, and evidently stood in considerable awe of his father, whose word was law. He was born with undescended testicles and claims to have been unaware of this until the age of 17, when he was operated upon for bilateral inguinal hernia. He was then told that he would be sterile, and discovered that he had no apparent testicles. For this he blames the doctors, saying that "medical science" has stopped him from having kids.

At first he was very resentful because the surgeons had refused to operate upon him and had sent him to me. Once this difficulty had been overcome he revealed himself as a rather bluff, jovial type of fellow, if anything rather over-familiar. But what most struck me, during the several interviews I had with him, was that, behind this outward mask of friendly familiarity, he was obviously abnormally afraid of me and deeply distrustful of my intentions. Apart from minor and more subtle indications of this, which cannot be readily recorded and reproduced, two little episodes during his second interview showed his attitude quite blatantly. While interviewing him, I opened the drawer of my desk and reached in for a sheet of paper. He immediately wisecracked, "What are you doing, Doctor? Getting out your revolver to shoot me?" Later he became increasingly preoccupied with the steel filing cabinet that stands in the corner of my office. He remarked that his firm made such articles and speculated upon whether mine was a good one. Suddenly he jumped up and, going over to it, started to pull open the drawers and to look inside. He tried to cover up his behaviour with a stream of patter to the effect that he was only interested in the mechanism and the workmanship because he was himself a craftsman. At his next interview he again displayed his distrustful attitude. On coming in, he looked all round and remarked that I had new chairs since his last visit. He then evinced great interest in the hospital outpatient department time-table that stood on my mantelpiece. He studied this most carefully, ignoring my repeated requests to him to be seated.

When he at length sat down, I tried to draw his attention to his suspicious attitude. I reviewed its various manifestations and told him that apparently he felt distrustful of me. But he would have none of it. He scouted the idea as ridiculous. His remark about the revolver was "just a joke." He was only interested in my filing cabinet as a craftsman, and so on. He further said it would be absurd not to trust a doctor, since medical men were only concerned to help their patients. He then changed the conversation and began to speak of my new chairs, saying jokingly that apparently the medical profession was doing quite well out of the National Health Service—buying new chairs out of working men's money. I pointed out that in this remark he again showed his distrust, but he simply laughed this off as ridiculous and told me that I twisted things round. He went straight on to tell a long story about a workmate who had collected funds for an outing for the men. Unknown to his workmates, this man had lost all the money on gambling. When the day of the outing drew near he tried to borrow money from my patient, who was treasurer of the share club. But my patient was cautious and refused. Later it all came out. As my patient remarked, he would have been "on the spot" if he hadn't been so cautious. Thus, by this narrative, he again indicated his cautious distrustful attitude by justifying it from his experience.

During his next interview he was aggressive in a demonstrative friendly manner, and in the next he

In short, whereas in ordinary practice you can often regard an illness as something foreign to the patient, something from outside that happened to him and can treat him successfully upon this basis, in dealing with a psychoneurotic illness this is very seldom the case. It is commonly said that a psychoneurosis always has its roots deeply buried in the patient's most intimate personality. It would be more correct to say that the psychoneurosis is only one manifestation, one outward expression, of his whole personality.

THREE CASES

In order to show more concretely what I mean, I shall now give some brief clinical extracts from three cases.

I

My first patient is a married woman of 30 with one child, a daughter 3 years of age. Her leading complaint is of attacks in which she feels as though she can get no air into her lungs, though there is no obstruction, and in which she feels she is about to die. The second symptom of which she complains is sexual frigidity: she finds sexual intercourse completely pleasureless and distasteful, and this is leading to serious difficulties with her husband. She also complains of inability to settle down contentedly to the rôle of housewife, and of periodic explosive outbursts of fury against her husband. She feels very sorry for him but she can go just so long and then she has to explode again.

She is a lean muscular girl, with a rather masterful, competent, and self-confident manner, who began her interview with me by stating that she had only come because of pressure from her husband and her family doctor. She said that she had always regarded "nerves" as something that one could and should deal with oneself by will-power.

She gave the following account of her history. She is an only child whose parents were divorced when she was about 14. Her mother is a quiet depressive submissive woman, quite unable to stand up for herself. Her father is a radio engineer, whom she describes as "brilliantly clever." He is a man of violent temper with a need to domineer. He likes people to tremble before him, she says, as her mother always did. The only way to deal with him is to stand up to him. This the patient early learned to do, but her mother never could. Violent rows between the parents were frequent in the patient's childhood, and she says that she used to stand up to her father on her mother's behalf; but I got the impression that she felt fonder of her father, whom she obviously greatly admires, than of her mother, though she keeps on friendly terms with both.

The patient herself feels that she takes after her father temperamentally, especially as regards his general aggressiveness and urge to dominate and his temper outbursts. At school she was very clever and in advance of her age—but, significantly perhaps, only in subjects outside her father's range, such as literature and history which he looked down upon, and not in mathematics and science which he regarded as the only true learning. She is intellectually ambitious. For some time she worked for an organisation concerned with political research, and during the war she was employed on intelligence and propaganda duties. Later she wanted to take up work connected with broadcasting, thus entering a domain connected with that of her father, the radio engineer. She had to give this up because of her domestic ties. As an attempt to compensate for the lack of a career, she has taken up part-time lecturing to evening classes.

At one time she was engaged to be married to a Roman Catholic, but she broke this off because, as she put it, she was "unable to accept doctrinal domination." Her husband she describes as a quiet long-suffering pessimistic type, who is very upset by her temper outbursts. Her marital situation, therefore, so far as temperament goes, presents a sort of reversed image of that of her parents.

I do not wish to go into much further detail in this case, but there is one other item of the history to be recorded. At the age of 17, while coming along a lonely lane across a common in the dusk, she was attacked by a man who ran at her, with exposed penis erect, and seized her by the throat. In this situation the memory of the father's ju-jutsu instructions came to her aid. She freed herself and ran.

Without entering into any deep discussion of the psychopathological possibilities in this case, I think the material presented should be sufficient to suggest to you that this girl's character has been moulded from an early age by her experience of her family interpersonal relationships along lines that make it excessively difficult for her now to adjust adequately to the rôle of housewife, wife, and mother. You may, perhaps, also feel that this is probably not just a question of a child consciously modelling herself after the pattern of her loved and admired father, but that, on the contrary, the more feminine position, as exemplified by her overwhelmed mother, may well have represented a position, not merely inferior but terrifyingly dangerous. From this fear-laden situation she is protected by her identification with her father. She will not readily give up this protection, and not without anguish. Against this background, I shall leave you to assess the significance of her "shock"—the abortive sexual assault when she was 17.

II

If my first case has given you some idea of the personal historical background of a psychoneurosis and of the psychic precipitation of such history in the form of character drives, I hope that my next will suggest to you how a patient may be expected to react to the threat of treatment.

This case is again a married woman. She is 29 and she has one child. She complains of abdominal pains and discomfort, headaches, giddiness, double vision, and impaired concentration. A duodenal ulcer has been demonstrated radiologically, but her other symptoms are regarded as hysterical (during testing her vision is sometimes not merely double, but even triple!) I saw her briefly in a medical ward and I told her that I had no doubt some of her symptoms were due to emotional stresses and that these might even have some bearing upon her duodenal ulceration, and that if she felt she wanted help in understanding and dealing with these troubles she might consider getting in touch with my department.

A month later she presented herself for an outpatient consultation. She is a very small brunette woman, who has been pretty and is still not unattractive. She describes herself as having been treated by her family as a spoilt and pretty little doll, and this is probably a fair enough description. She is the youngest of four and is the only girl. Her three brothers are much senior to her, the eldest by 14 years. She has always resented her status in the family, and felt this particularly bitterly when she was about 11 years old. At that time her mother had to go away for a while to hospital. The patient expected, during her absence, to play the part of mother, but was frustrated in this, because the family did not take her so seriously as she wished. She is an intellectually ambitious person, who chafes at not having a career and dreams of taking various courses of training, if her health permits and if she can find enough spare time.

She enters my office with a brightly smiling face and a sort of challengingly semi-flirtatious manner. She is rather tense, and eyes me keenly as a fencer might his adversary, ready to parry an awaited thrust, determined not to be caught off her guard. I invite her to tell me about herself, but this does not suit her. She tries to make me ask the questions. It has to be a sort of contest, in which I should try to find out what I can about her, a sort of "twenty questions" game. But I point out to her the defensive nature of this attitude, and tell her this is not the best way to set about our business, and I urge her just to tell me, if she can, what troubles her. She then begins, "My husband told me to ask you if I should stop reading books about psychoanalysis and psychology." Thus she again avoids the initiative. I point this out to her and suggest that she must have some reason of her own for coming to see me. She then says that she has come because the doctors have assured her that there is "nothing whatever organically wrong" with her, and that her pains are entirely due to emotional disturbances. As she has been unable to track down the cause of these for herself, and "as the doctors must understand such matters better" than she, she has come for help. I point out to her that there appears to be a discrepancy here; her medical records show that a duodenal ulcer has been present and has been demonstrated radiologically; therefore it is unlikely that the doctors have said there is nothing whatever organically wrong. She agrees that this is so, that she has exaggerated, and I point out the tendency to try to score a debating point by extending her opponent's premise, and so to set a trap for later use. This elicits a somewhat abashed and deprecatory laugh. With some difficulty I manage to lead the conversation around over various relevant topics, but the atmosphere is never really easy. All the time there is the underlying feeling that one is engaged in a sort of verbal sparring or fencing match.

While talking of her psychological reading, she had used the phrase "amateur psychoanalysis." When we later returned to the topic she tried to develop the argument that her interest in such literature was merely a part of her wide interest in books. She had many literary interests and this was just one of them. When I said, "But you call this amateur psychoanalysis," she thought that I was referring not to her book reading but to our interview, and hastened to assure me that I had misunderstood her meaning. Throughout the interview she was hypocritically respectful, in such a way that the irony was almost directly apparent. She asked to be placed on our waiting-list for treatment, and departed, still wearing her brightly smiling mask.

III

If my first case has given you some hint of the basic importance of personality, its intimate connection with neurotic suffering, and the long course of its development, beginning in childhood and serving as a protection from the particular stresses then encountered, I hope that the second will have given you an impression of how carefully a patient strives to preserve this personality inviolate from exploration. My third is intended to develop this point a little further by illustrating how blind a patient may be to his own attitudes, or behaviour, and how he can maintain this blindness in the face of repeated demonstrations.

The patient is a married man of 44, who was originally referred to the surgical specialist on account of pain in the site of an old hernia repair operation, carried out 20 years previously.

I shall omit most of his history and symptoms for my present purpose is only to describe to you some of his behaviour during interviews. There are a few points however that may make his attitude a little more understandable. He was brought up in a strict patriarchal type of family, and evidently stood in considerable awe of his father, whose word was law. He was born with undescended testicles and claims to have been unaware of this until the age of 17, when he was operated upon for bilateral inguinal hernia. He was then told that he would be sterile, and discovered that he had no apparent testicles. For this he blames the doctors, saying that "medical science" has stopped him from having kids.

At first he was very resentful because the surgeons had refused to operate upon him and had sent him to me. Once this difficulty had been overcome he revealed himself as a rather bluff, jovial type of fellow, if anything rather over-familiar. But what most struck me, during the several interviews I had with him, was that, behind this outward mask of friendly familiarity, he was obviously abnormally afraid of me and deeply distrustful of my intentions. Apart from minor and more subtle indications of this, which cannot be readily recorded and reproduced, two little episodes during his second interview showed his attitude quite blatantly. While interviewing him, I opened the drawer of my desk and reached in for a sheet of paper. He immediately wisecracked, "What are you doing, Doctor? Getting out your revolver to shoot me?" Later he became increasingly preoccupied with the steel filing cabinet that stands in the corner of my office. He remarked that his firm made such articles and speculated upon whether mine was a good one. Suddenly he jumped up and, going over to it, started to pull open the drawers and to look inside. He tried to cover up his behaviour with a stream of patter to the effect that he was only interested in the mechanism and the workmanship because he was himself a craftsman. At his next interview he again displayed his distrustful attitude. On coming in, he looked all round and remarked that I had new chairs since his last visit. He then evinced great interest in the hospital outpatient department time-table that stood on my mantelpiece. He studied this most carefully, ignoring my repeated requests to him to be seated.

When he at length sat down, I tried to draw his attention to his suspicious attitude. I reviewed its various manifestations and told him that apparently he felt distrustful of me. But he would have none of it. He scouted the idea as ridiculous. His remark about the revolver was "just a joke." He was only interested in my filing cabinet as a craftsman, and so on. He further said it would be absurd not to trust a doctor, since medical men were only concerned to help their patients. He then changed the conversation and began to speak of my new chairs, saying jokingly that apparently the medical profession was doing quite well out of the National Health Service—buying new chairs out of working men's money. I pointed out that in this remark he again showed his distrust, but he simply laughed this off as ridiculous and told me that I twisted things round. He went straight on to tell a long story about a workmate who had collected funds for an outing for the men. Unknown to his workmates, this man had lost all the money on gambling. When the day of the outing drew near he tried to borrow money from my patient, who was treasurer of the share club. But my patient was cautious and refused. Later it all came out. As my patient remarked, he would have been "on the spot" if he hadn't been so cautious. Thus, by this narrative, he again indicated his cautious distrustful attitude by justifying it from his experience.

During his next interview he was aggressive in a demonstrative friendly manner, and in the next he

In short, whereas in ordinary practice you can often regard an illness as something foreign to the patient, something from outside that happened to him and can treat him successfully upon this basis, in dealing with a psychoneurotic illness this is very *seldom the case*. It is commonly said that a psychoneurosis always has its roots deeply buried in the patient's most intimate personality. It would be more correct to say that the psychoneurosis is only one manifestation, one outward expression, of his whole personality.

THREE CASES

In order to show more concretely what I mean, I shall now give some brief clinical extracts from three cases.

I

My first patient is a married woman of 30 with one child, a daughter 3 years of age. Her leading complaint is of attacks in which she feels as though she can get no air into her lungs, though there is no obstruction, and in which she feels she is about to die. The second symptom of which she complains is sexual frigidity: she finds sexual intercourse completely pleasureless and distasteful, and this is leading to serious difficulties with her husband. She also complains of inability to settle down contentedly to the rôle of housewife, and of periodic explosive outbursts of fury against her husband. She feels very sorry for him but she can go just so long and then she has to explode again.

She is a lean muscular girl, with a rather masterful, competent, and self-confident manner, who began her interview with me by stating that she had only come because of pressure from her husband and her family doctor. She said that she had always regarded "nerves" as something that one could and should deal with oneself by will-power.

She gave the following account of her history. She is an only child whose parents were divorced when she was about 14. Her mother is a quiet depressive submissive woman, quite unable to stand up for herself. Her father is a radio engineer, whom she describes as "brilliantly clever." He is a man of violent temper with a need to domineer. He likes people to tremble before him, she says, as her mother always did. The only way to deal with him is to stand up to him. This the patient early learned to do, but her mother never could. Violent rows between the parents were frequent in the patient's childhood, and she says that she used to stand up to her father on her mother's behalf; but I got the impression that she felt fonder of her father, whom she obviously greatly admires, than of her mother, though she keeps on friendly terms with both.

The patient herself feels that she takes after her father temperamentally, especially as regards his general aggressiveness and urge to dominate and his temper outbursts. At school she was very clever and in advance of her age—but, significantly perhaps, only in subjects outside her father's range, such as literature and history which he looked down upon, and not in mathematics and science which he regarded as the only true learning. She is intellectually ambitious. For some time she worked for an organisation concerned with political research, and during the war she was employed on intelligence and propaganda duties. Later she wanted to take up work connected with broadcasting, thus entering a domain connected with that of her father, the radio engineer. She had to give this up because of her domestic ties. As an attempt to compensate for the lack of a career, she has taken up part-time lecturing to evening classes.

At one time she was engaged to be married to a Roman Catholic, but she broke this off because, as she put it, she was "unable to accept doctrinal domination." Her husband she describes as a quiet long-suffering pessimistic type, who is very upset by her temper outbursts. Her marital situation, therefore, so far as temperament goes, presents a sort of reversed image of that of her parents.

I do not wish to go into much further detail in this case, but there is one other item of the history to be recorded. At the age of 17, while coming along a lonely lane across a common in the dusk, she was attacked by a man who ran at her, with exposed penis erect, and seized her by the throat. In this situation the memory of the father's ju-jutsu instructions came to her aid. She freed herself and ran.

Without entering into any deep discussion of the psychopathological possibilities in this case, I think the material presented should be sufficient to suggest to you that this girl's character has been moulded from an early age by her experience of her family interpersonal relationships along lines that make it excessively difficult for her now to adjust adequately to the rôle of housewife, wife, and mother. You may, perhaps, also feel that this is probably not just a question of a child consciously modelling herself after the pattern of her loved and admired father, but that, on the contrary, the more feminine position, as exemplified by her overwhelmed mother, may well have represented a position, not merely inferior but terrifyingly dangerous. From this fear-laden situation she is protected by her identification with her father. She will not readily give up this protection, and not without anguish. Against this background, I shall leave you to assess the significance of her "shock"—the abortive sexual assault when she was 17.

II

If my first case has given you some idea of the personal historical background of a psychoneurosis and of the psychic precipitation of such history in the form of character drives, I hope that my next will suggest to you how a patient may be expected to react to the threat of treatment.

This case is again a married woman. She is 29 and she has one child. She complains of abdominal pains and discomfort, headaches, giddiness, double vision, and impaired concentration. A duodenal ulcer has been demonstrated radiologically, but her other symptoms are regarded as hysterical (during testing her vision is sometimes not merely double, but even triple!) I saw her briefly in a medical ward and I told her that I had no doubt some of her symptoms were due to emotional stresses and that these might even have some bearing upon her duodenal ulceration, and that if she felt she wanted help in understanding and dealing with these troubles she might consider getting in touch with my department.

A month later she presented herself for an outpatient consultation. She is a very small brunette woman, who has been pretty and is still not unattractive. She describes herself as having been treated by her family as a spoilt and pretty little doll, and this is probably a fair enough description. She is the youngest of four and is the only girl. Her three brothers are much senior to her, the eldest by 14 years. She has always resented her status in the family, and felt this particularly bitterly when she was about 11 years old. At that time her mother had to go away for a while to hospital. The patient expected, during her absence, to play the part of mother, but was frustrated in this, because the family did not take her so seriously as she wished. She is an intellectually ambitious person, who chafes at not having a career and dreams of taking various courses of training, if her health permits and if she can find enough spare time.

These resins are suitable for laminating and casting techniques, and workers in the United States have lately been able to produce a resin which is not air-inhibited during curing. Air-inhibition has hindered the fabrication of structures from these resins, since the surface of the moulding had to be protected from the oxygen of the air by a membrane such as 'Cellophane' or 'Polythene,' and a vacuum applied to remove any trapped pockets of air.

CASTINGS

Until recently it has been difficult to reproduce the internal structures of organs and joints. Attempts have been made with low-temperature fusible alloys, such as Wood's metal, plaster-of-paris, wax, and 'Neoprene.' Each has its advantages and disadvantages. Penetration of the organ has been difficult with alloys, plasters, and waxes, and the cast is insufficiently rigid when emulsions such as neoprene are employed. Cellulosic injection materials have been used, but in this case the difficulty has been to evaporate the solvent; and the casts so formed were shrunken and fragile.

In France, Baud and Duprez[1] have described a method of casting in which they inject poly-methyl methacrylate dissolved in acetone, and use various dyes soluble in organic solvents. With polyester resins, it is not necessary to suspend the organ in air for 24 hours, there being no solvent to evaporate; and shrinkage is consequently reduced. The polyester resin which we have found most suitable has been 'Marco 61c.'[2] The following casting mixture, which has a gelling time of about 1 hour, is satisfactory:

Resin 61c	100	Parts by weight.
Monomer C	34	
Catalyst benzoyl peroxide ..	3	

The gelling time varies according to room-temperature. and can also be modified by altering the catalyst content. The monomer and resin may be mixed and stored in a refrigerator for 36 hours if the catalyst has not been added.

The following examples are given to show how the technique may be altered to suit different organs.

In making the cast of the sheep's lung (fig. 1) the fresh specimen was suspended in a water-bath, and a glass connection was stitched into the pulmonary vessels and the trachea. To each connection a T-junction was attached, one limb of which went to a vacuum pump and the other to a length of rubber tubing connected with a funnel. Three funnels were thus necessary, each being filled with resin containing the colour desired in the system.

The height of the funnels could be varied so that if one system was found to be filling too rapidly adjustments to the gravity feed could be made. It has been found that the venous system of an organ fills most readily and the arterial supply slowly. Before running in the resin, a partial vacuum was applied to each system, so as to remove excess fluids and air. Complete evacuation of the specimen was not possible, and since the aim was only to fill the organ as far as the secondary bronchi, the remaining fluids acted as buffers to prevent the resin from reaching the terminal spaces. If the terminal spaces are completely filled, it is difficult to dissolve away the tissue by acid in such a complex organ.

The clip on feed A (fig. 2) was closed before applying the vacuum, the funnel and tube being then filled with resin. With the vacuum still applied, clip A was opened and the resin allowed to flow as far as the T-junction, when clip B was closed. By this means, the amount of air pushed into the specimen was reduced to a minimum. All three systems were manipulated in this way. The arterial resin was allowed to flow first, that for the trachea next, and finally the veins.

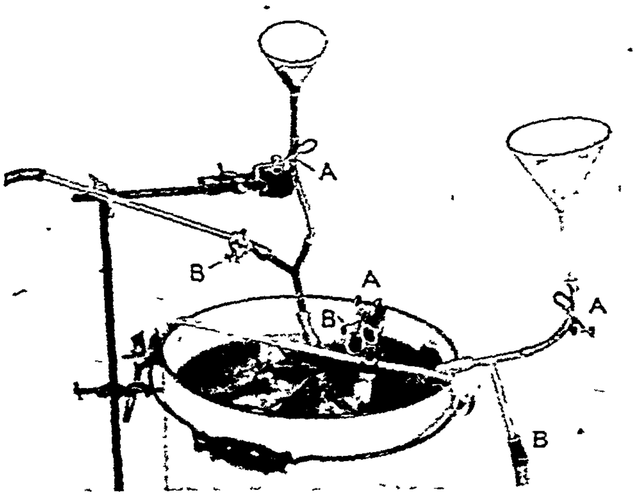

Fig. 2—Lungs floating in water, with connections sewn in place. Two filling funnels are shown.

Small organs, such as kidneys (fig. 3), can be injected with a syringe, but the pressure exerted is liable to burst the vessels and the gravity feed method has proved more satisfactory. The specimen is left to polymerise overnight and on the following day is placed in a bath of concentrated hydrochloric acid. It must be washed each day so that the acid can act on the deeper structures.

In the case of joints, such as the knee-joint, multiple injections may be needed. The resin should be injected

referred to "medical science having stopped him having kids," thus indicating some of the grounds for his distrust of me. He also interested himself in the poker that lay in my fireplace. On his way out he opened the door and met my assistant on the landing outside. He at once started back, flinging up his hands in a defensive posture, and jokingly saying "Oh! I thought you were going to do me!" Throughout his eight interviews this patient was never able to see or to admit that he felt at all distrustful or on his guard towards me.

COMMENT

The lessons that I want to draw are these. The symptoms of a psychoneurosis are themselves of minor import relative to the underlying disorder, tormenting though they may be—just, for instance, as thirst may be in diabetes mellitus. The underlying disorder is an abnormality of character or personality leading to an inability to adjust to the life situation in which the patient finds himself. Here it should be added, though the point is not illustrated in this paper, that the particular character drives are themselves very often responsible for bringing about just those life situations which at first glance seem to be the source of the patient's distress.

Treatment therefore, if it is to be more than a placebo, must involve some readjustment in the character. Yet we have seen that character formation is a process that starts in early childhood as a protection against the various serious anxieties of that time, which anxieties it continues to contain in adult life, having by then become more or less set and resistive to change. We have seen that patients energetically defend themselves against a nearer approach to their character disorders, and that they remain blind to indications of their personal attitudes that are startlingly apparent to other people, and maintain this blindness actively in resistance to attempts to dispel it. It may also seem likely to you that, once adult years are reached, the possibility of change begins to diminish, different characters varying in the degree of their rigidity, and therefore in their susceptibility to radical psychiatric treatment.

The *general conclusion surely must be* that one or two talks with a psychiatrist are unlikely to effect any very fundamental change in a psychoneurotic patient. In the end we must put away our lingering hopes of omnipotent thought treatments, and recognise that reality requires long and painstaking and difficult work if we wish to treat those who suffer from psychoneurosis. We must also be still more realistic and realise that at present, apart from a little palliation, many cannot be treated at all.

"... The human being is born at a very early stage of development by comparison with other mammals. He is dependent on parental care for a far greater proportion of his average life than any other higher animal. During this period, his normal social and intellectual development depends almost wholly on the stability of the family, and on the dynamics of the relationships which exist within it. Failure of these produces a personality which is itself incapable of responsible social attitudes. The family is a uterus from which the child must not be expelled until gestation is over. Delinquency as we know it, whether it assumes forms of which the law takes cognisance, or whether it is of the more dangerous kind which manifests itself in aggression, the desire for dominance over others, obsessional patterns of behaviour, and irresponsible conduct through and within existing conventions of behaviour, is a form of prematurity. It is also one of our chief endemic diseases."—Dr. ALEX COMFORT, in *Sexual Behaviour in Society.* London, 1950; p. 50.

USE OF POLYESTER RESINS IN MEDICINE

JOHN T. SCALES

M.R.C.S.

PLASTICS RESEARCH UNIT, INSTITUTE OF ORTHOPÆDICS (UNIVERSITY OF LONDON), STANMORE, MIDDLESEX

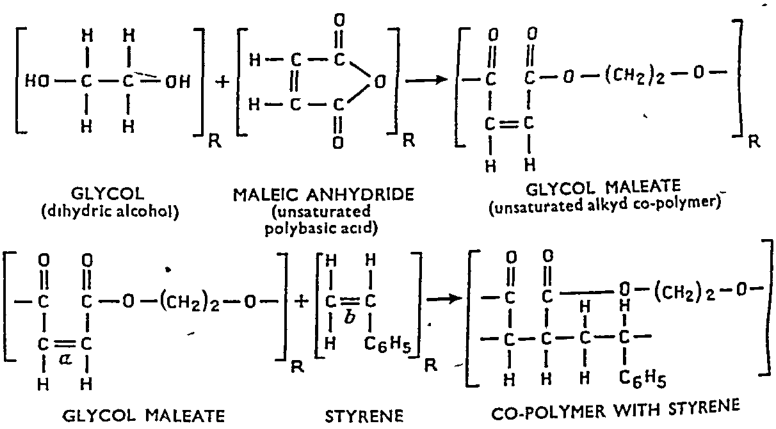
With illustrations on plate

THE use of polyester resins has been under investigation for the manufacture of orthopædic appliances. At an early stage in the experimental work however, it was realised that these synthetic materials had, in addition, possibilities in other fields of medicine. This paper deals with their use for the internal casting, embedding, and reproduction of anatomical and pathological specimens, as well as splint-making.

CHEMISTRY

These synthetic compounds are produced in industry for a number of purposes, such as the manufacture of paint, electrical insulation, the hulls of boats, and aircraft components.

The resins are esters of polybasic unsaturated organic acids (e.g., fumaric, maleic, or itaconic), or their anhydrides, with saturated dihydric alcohols such as glycol. The thermoplastic resins, primarily formed, are known as unsaturated alkyd polymers and are "cured" (or set) into a thermoset structure by co-polymerisation with unsaturated cross-linking agents such as styrene, cyclopentadiene, or methyl-methacrylate.



At points marked *a* and *b* in the accompanying formulæ the double bonds are activated, and cross-linking occurs. This reaction is brought about by the action of a catalyst such as benzoyl peroxide and in some cases with the aid of energy in the form of heat and/or ultra-violet light. The final plastics formed have a three-dimensional network structure, and the properties of a thermo-setting resin. These cross-linked polymers are characteristic in that:

During polymerisation no by-products are produced. The polymerisation can be made to occur at low temperatures. The rate of polymerisation can be varied. No positive pressures are required unless a laminating process is used.

Viscosity of the resin mixture, before polymerisation, can be varied by altering the proportions of the monomer and alkyd resin.

The plastic formed after polymerisation is a thermo-setting material. Some types of resins can be made to link with themselves so forming a network structure without the addition of a material such as styrene.

The exact chemistry of these resins is subject to industrial patents and is therefore not disclosed by industry; but the foregoing account indicates the reactions involved.

from the lowest point of the joint and during this procedure the joint should be moved so that the resin is able to flow into all the reflections of the synovial membrane.

An air-vent (which can be a needle, with a clip on a piece of rubber-tubing) is essential at the highest part of the joint to make complete filling possible. As soon as the resin appears through the vent, the clip is closed and a few more cubic centimetres of resin are run in, so as to ensure that the joint cavity is fully distended. Care should be taken that there is no further movement of the specimen: otherwise the resin, if it is beginning to gel, will crack. Joint cavities are most easily filled by using a syringe.

As the resin mixture is a liquid, it permeates the organ well and reproduces its structure with extreme accuracy.

EMBEDDING SPECIMENS

The usual way of mounting specimens has been to put them into preserving fluid in heavy glass jars often with poor optical properties; and by the time a large specimen is mounted it often weighs several pounds. The introduction of 'Perspex' specimen jars meant better mounting of specimens and considerable saving in weight. In the last 3–4 years many people have been trying, with varying degrees of success, to mount specimens in transparent resins so that all aspects can be equally well viewed. Resin embedding allows for considerable saving in shelf space and weight. Specimens have been embedded using Marco 26c. The method is simple and can be applied to wet specimens. The vole (fig. 4) had been preserved in 5% formalin (aqueous solution) for some weeks; before being embedded it was placed in 95% alcohol for 15 min., and then transferred to chloroform for a further 15 min.; after this it was dipped in 'Monomer C.' A base of resin was cast into a glass vessel of suitable size. The depth of such a base should not be more than $^1/_4$–$^1/_2$ in., and it is important that casting should be done in a dust-free atmosphere; otherwise, in the final result, a joint line will be visible. When the base had gelled, the specimen, having been dipped in monomer C, was placed on it and more resin added so as to give a layer above the specimen equal to that of the base.

Care must be taken during this last procedure that air-bubbles are not trapped; the chance of trapping bubbles can be greatly reduced by agitating the vessel in which the embedding is being done. Should bubbles still be present, the whole is placed in a container to which a vacuum can be applied. It may be found that during the mixing of the resin a large number of air-bubbles may appear, in which case the resin should be subjected to a vacuum, when the bubbles will disperse. The bursting of air bubbles by means of a metal or glass instrument, after the specimen has been embedded, is not advisable, even though the resin is still liquid, for lines may sometimes appear as a result.

In polymerisation reactions, the resulting polymer always contracts; and the amount of contraction with this particular resin is about 9%. Contraction produces a concave upper surface to the block, and sufficient resin should therefore be used to allow for grinding and polishing to get rid of the concavity. The exposed surface is slightly tacky after the resin has cured, owing to air-inhibition; but this surface is removed during polishing. After grinding, metal-polish or jeweller's rouge is used.

As the reaction is exothermic, the rate at which the resin mixture cures should be controlled. This can be done by altering the quantity of catalyst.

A suitable embedding mixture is as follows:

Resin 26c	100	Parts by weight.
Monomer C	40	
Catalyst HCH	0·75	
Accelerator E	1·5	

The above can be stored for 36 hours in a refrigerator, but will gel in about 12 hours if the temperature is raised to 60–70°F.

REPRODUCTION OF BONES

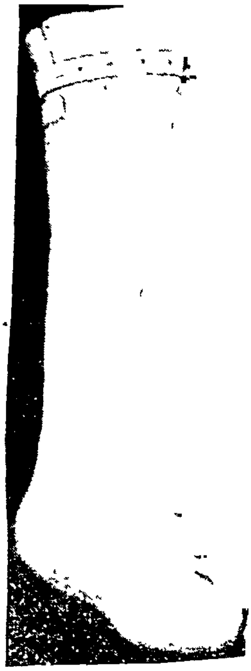

Fig. 6—Polyester resin prosthesis for Chopart's amputation.

Bones can be reproduced in resin. The bone to be copied is suspended in a suitable container which allows a minimum clearance all round of $^1/_2$ in. The container should then be placed in an oven with a regulator set at 100°C, so that as much air as possible is driven out of the bone; alternatively the bone can be dipped in hot liquid petroleum jelly. This procedure ensures that air-bubbles are not produced in the mould later. Various mould-forming materials may be used, and most require heat to make them into a flexible solid. The following have been tried and found satisfactory: polyvinyl chloride paste, 'Vinamould,'[3] and latex. We have found 'Vinamould H.M.C. 21' most satisfactory for our purpose, but if a number of castings are to be made from the same mould, latex should be used, because polyester resins attack vinyl compounds. The following

is a suitable mixture, the French chalk and wood flour acting as a filler and pigment combined.

	Parts by weight.
Resin 61c	100
Monomer C	40
Catalyst	3
French chalk and wood flour	8 (80–20 %)

The resin is left to polymerise and the finished moulding is removed (fig. 5). The point where the resin is poured in may need polishing. This method of bone reproduction is simple and requires little apparatus.

ORTHOPÆDIC APPLIANCES

For making orthopædic splints either Marco 61c or 'Nuron'[4] is used, preferably with a cheap filler such as wood flour. A plaster cast of the part is made in the usual manner and from this a plaster-of-paris male mould is formed which is then covered with a suitable "release," such as cellulose acetate solution. This is allowed to dry so as to form a film, which will prevent the laminate from adhering to the cast. These resins produce light-weight strong rigid appliances (fig. 6). In America similar resins have been used for the construction of artificial limbs by the Northrop Aircraft Company.

The resin, in combination with glass-fibre cloth, is cured in a laminating technique; cotton or paper or other materials can be used but with these strength falls considerably. The glass-fibre cloth should be tailored to the shape, and should preferably be in the form of a woven material with plenty of bias. The resin is applied to the successive layers of the cloth with a paint-brush, until the requisite thickness for the appliance is built up. With some resins (e.g., Nuron) ultraviolet light, or heat up to 100°C is required. A positive pressure can be applied to the outside of the laminate by winding round it strips of a flexible material such as cellophane or polythene. The results are then better because air-pockets are excluded and air-inhibition avoided.

In another method—the "bag" technique—rubber or latex bags which accurately fit the cast are used. With some resins (e.g., Nuron) the rubber must not be allowed to come into contact with the resin because it inhibits curing. With such resins therefore, polythene bags which cause no inhibition and transmit ultraviolet light, should be used.

Much credit is due to my assistant Mr. T. Fisher for his part in this work. I also wish to thank the industrial concerns mentioned for technical information and supply of materials, Mr. J. Nangle, F.R.C.S., for fig. 2, and Mr. R. J., W. Whitley, A.R.P.S., for figs. 5 and 6.

SCATTERED MUSCLE NECROSES ASSOCIATED WITH POST-TRAUMATIC URÆMIA

G. L. ROBINSON
M.D. Camb.
PATHOLOGIST, SEAMEN'S HOSPITAL, GREENWICH

With illustration on plate

THIS article describes patches of ischæmia in the skeletal muscles of 2 soldiers who died, with high blood-urea levels, after receiving wounds in the North African campaign.[1]

CASE-HISTORIES

Case 1.—A German youth was wounded by bullets in the hand and leg on Feb. 1, 1943. He was exsanguinated when operated on next day and was transfused with plasma. Sulphonamide was applied; open fractures of the right tibia and fibula, and the left wrist, were encased in plaster. He was then transferred to a general hospital, where he showed much fear and seemed hyperæsthetic, but did not become seriously ill till Feb. 6, when examination revealed no cause for his distress either in his wounds or general condition. His respiration-rate was rapid, his blood-pressure normal, and he was tender to pressure in many places. At first restless, he soon became delirious and incontinent. Pulse and temperature were subnormal throughout. On Feb. 9, a white blood-count (capillary) showed 80,000 leucocytes per c.mm., 91% polymorphs. No malarial parasites were seen in the smear. Blood-culture next day, when intravenous plasma and saline infusion was begun, remained sterile; this venous sample contained 50,000 leucocytes per c.mm., 352 mg. urea per 100 ml., and the packed red-cell volume was judged to be about 15% after hand-centrifuging.

He died on Feb. 10, and *necropsy* was performed about twelve hours later. The body was that of a small, spare, but well-developed young man, with the left forearm and right leg in plaster. The skin was sallow. An abrasion, 5 × 3 cm., was present over the left great trochanter, another above the right anterior superior iliac spine, and numerous smaller ones over both buttocks. Removal of plasters showed a compound comminuted fracture of the right tibia and fibula with an open anterior wound exposing the interior of the leg down to the soleus. A deep gash had severed the extensor tendons over the left wrist. Both wounds were dry and clean. When the body was opened, yellowish-white areas of necrosis were seen in the pectoral muscles; 2 in. of the costal end of the left pectoralis minor had the appearance of "white meat," with a sharp line of demarcation between this and the normal tissue (see figure). The decolorised muscle was dry and friable and the fascia was adherent over it. Distally in the same muscle a band of similar change occupied the whole breadth. Other pale patches were found in the left pectoralis major, both right pectorals, both recti abdominis, left psoas, right biceps brachii (where the affected zone formed a central pencil through the muscle), left quadriceps, and in a musculo-tendinous junction exposed in the leg wound. They were not found in the right quadriceps, left biceps brachii, sacrospinalis, or hamstrings and adductors of the left thigh.

The organs generally were free from gross abnormality. There were small zones of collapse at the edges of the lung bases. The mesenteric and cervical lymph-nodes were slightly enlarged. The spleen was normal in size and its pattern clear. No abnormalities were found in arteries, veins, heart, suprarenals, or alimentary canal. The brain was œdematous, the middle ears clean. A firm ante-mortem clot, 6 cm. long by 2 cm. in diameter was found coiled in the nasopharynx. The bladder contained about $^1/_2$ pint of clear urine which showed only a trace of albumin and no casts. The kidneys (right, 11 × 5 × 4 cm., weight 157 g., left 9·5 × 6 × 4 cm., weight 128 g.) were pale with prominent stellate veins. Cortex was of normal width with yellowish-grey swollen cut surface, radially streaked by congested vessels. The pyramids were very congested but slightly depressed. The blood-urea was over 375 mg. per 100 ml. the Weil-Felix reaction negative, and *Clostridium welchii* was cultured from various muscles.

pallid, sometimes mottled by hæmorrhage, and sharply demarcated, like an infarct, from normal muscle.

As regards the renal lesions, the only point of special interest appears to be the difference between the kidneys of the two cases. The standard features were present in both. but in case 2 were much modified by the generally congestive termination. The kidney of case 1 was the more typical "crush type," while that of case 2 rather resembled Bratton's (1941) case 7. Whether or not oliguria developed at any stage in either case is unknown.

There is little doubt that the muscle necroses in case 2 would have passed unnoticed but for the special search prompted by the finding of the striking "fish muscle" patches in the severe case 1, where anæmia and leucocytosis were also correspondingly greater. Some of the original sections from case 1 showed slight signs of intimal vascular lesions. and were picked out for further study; but this material was lost.

Anæmia. leucocytosis, and internal hæmorrhages are *peculiar features* of these cases, lying outside the renal syndrome as generally described. Hæmoglobin levels of 50% are given by Parsons (1945); but case 1 was more anæmic than this. The high concentration of intravascular inflammatory cells in the sections of most tissues recalls the similar findings of Woods (1946) in kidneys from cases of carbon tetrachloride poisoning.

SUMMARY

Two cases of post-traumatic uræmia. seen in the North African campaign of the late war. are reported because they showed patches of muscle necrosis distant from the site of trauma. No parallel reports have been found.

DISSECTING AORTIC ANEURYSM SIMULATING ARTERIAL EMBOLISM

REPORT OF TWO CASES

G. J. FRAENKEL

NOTTINGHAM GENERAL HOSPITAL

With illustrations on plate

DISSECTING aneurysm of the aorta is seldom seen in the surgical ward; but it can produce signs and symptoms, referable to the limbs and to the abdomen, which may mislead the surgeon. In the differential diagnosis of acute peripheral vascular occlusion, a dissecting aneurysm is not usually considered; but we report here two cases in which this condition caused signs and symptoms which led to a diagnosis of embolism.

Shennan (1934), in his review of the literature. found several cases in which there was paraplegia, sometimes associated with incontinence, suggesting cord involvement. but in three the evidence pointed to occlusion of the lumen of the aorta. One of these went on to gangrene of the lower limbs (Gordon 1863). In another case, the dissection was localised to the right internal iliac and femoral arteries, producing gangrene (Turner 1829).

Of Shennan's own series, case 10 is of interest. A man aged 40 was admitted with pain and loss of power in the right arm, and also severe pain across the middle of the body. An embolus was removed from the axillary artery, but next day he died. Necropsy revealed a dissecting aneurysm of the aorta; the dissection had apparently started when he complained of the pain across the body. A somewhat similar case was reported by Glendy et al. (1937). A right iliac embolus was diagnosed, and at operation a 3-inch clot was removed. but no blood flowed from the proximal segment. A dissecting aneurysm was found post mortem. A second case of aneurysm diagnosed as an iliac embolus died during an embolectomy.

Kellogg and Heald (1933) reported the case of a patient who died with gangrene of the lower limbs. Two other cases are reported by the Massachusetts General Hospital (1945) and Shucksmith and McPherson (1949), both fatal.

CASE-RECORDS

Case 1.—Mrs. A, aged 32, was admitted on Feb. 2, 1947, with a history of collapse in a shop 24 hours previously: she had found herself unable to move her right leg, and had then developed some pain at the bottom of her back and vomited. For seven years she had had "kidney trouble and high blood-pressure" and two years previously a pregnancy had been terminated and sterilisation performed. Recently she had suffered from shortness of breath, vomiting, and severe headaches relieved by venesection.

The right leg was cold, powerless, anæsthetic, and patchy blue and white below the knee. A feeble pulse was felt in the femoral artery at the inguinal ligament but no other pulsation in this leg. The left leg appeared normal with full pulses. The heart was clinically enlarged; blood-pressure 170/120 mm. Hg; pulse-rate regular at 100. There was conspicuous pulsation in the neck, a systolic thrill at the base of the heart, and an apical systolic murmur. The liver was enlarged three finger-breadths.

A diagnosis of embolus of the right femoral artery was confidently made, and in spite of the time which had already elapsed (24 hours) it was judged that there might be a chance of saving some of the limb by immediate embolectomy (after further experience of vascular occlusion the same decision might not be made now). Accordingly the femoral artery with all its branches was displayed (G. J. F.) in the femoral triangle under 2% procaine infiltration. It was not pulsating and no clot was felt. It was opened proximal to the profunda branch; no clot was found and the flow of blood was very feeble, but it was thought that this might suffice to tide the limb over. To make certain that no embolus had been forced downward during the initial manipulations, the artery was now opened lower down, with similar findings. The artery was repaired and the wound closed. Heparin was given. The patient died 12 hours after admission.

Necropsy was performed, but unfortunately purely with the object of ascertaining the cause of death for H.M. Coroner and therefore very limited. A dissecting aneurysm of the aorta was found, beginning close to the heart in the pericardium and extending as far as the diaphragm. The lower aorta appears not to have been examined. The cause of death as given to the coroner was rupture of aortic aneurysm with hæmopericardium.

We felt little doubt that the dissecting aneurysm must have extended to the neighbourhood of the bifurcation of the aorta and interfered mechanically with the flow of blood to the right iliac artery to a considerable extent.

Case 2.—A man, aged 51, was admitted on May 18, 1949, at 12 noon: 75 minutes previously, he had collapsed with sudden pain in the precordium and down the right arm. He was drowsy, rather shocked, and cyanosed. The right arm was white, cold, anæsthetic, and paralysed. No pulse could be felt at the wrist or over the brachial artery, but the subclavian pulse was present. The left radial pulse was slow, regular, and of fair volume. The heart sounds were faint, no abnormal sounds being heard. Blood-pressure 110/70. He had a history of hypertension.

Micropathology.—Sections of the basal ganglia showed a slightly unusual number of intravascular cells (many of them polymorphs); and so did sections of the suprarenal, where there was some congestion with a few extravasated red cells in the cortex. The white areas in the voluntary muscles showed an aseptic necrosis, and only that from the wound was extensively invaded by granulation tissue; but although there was practically no exudate, many vessels contained numerous inflammatory cells—sometimes up to a dozen polymorphs were compressed into Indian file by an enclosing capillary. The muscle-fibres showed various stages of degeneration: some were foamy or reticulated, some cracked transversely, some marked by wavy ribs of hæmatoxyphil granules derived apparently from the striæ, and some swollen into ill-defined hæmatoxyphil ovoid masses. There were no signs of pre-existing disease in sections of the kidney, whose main abnormality was seen to be a tubular degeneration, amounting to desquamation in places. There were scattered casts of albuminous debris, sometimes pigmented and granular in the lower nephron. Albuminous exudate was present in most of Bowman's capsules, where it tended to form hyaline globules lining the capsular membrane; and this itself showed hyaline swelling in places. The tufts did not appear abnormal, except for occasional polymorphs within their capillaries. The interstitial tissue contained lymphocytic foci. The medullary vessels were congested and many contained a rather large number of monocytes and polymorphs. A very few radially striated grey inorganic spheroids were seen in the tubules; similar formations were noted by Parsons (1945) in kidneys from cases of post-traumatic uræmia, and by Woods (1946) in those of cases of carbon tetrachloride poisoning. They could not have been sulphonamide, since they were sought for, and found, in kidney sections from patients who had received none. Stains for free iron and for organisms were negative.

Case 2.—An English corporal had his right arm shattered by a shell fragment on April 10, 1943. Surgical amputation was done after an unknown period, and he was transfused with plasma but not blood. On April 15 he became restless and distressed without obvious cause, and his respiration-rate rose. His blood-pressure was then 132/95, pulse-rate 64, and hæmoglobin 50% (Haldane). It is not remembered whether he was tender on pressure. Blood-urea on April 19 was 322 mg. per 100 ml. He received intravenous glucose-saline during the last 15 hours before his death on April 20, on which day his hæmoglobin was still 50%, red cells 2,400,000 per c.mm., white cells 25,000 per c.mm., polymorphs 79%; there was an excess of platelets in the blood-smear. The urine was clear and pale, containing a trace of albumin only.

Necropsy took place on the day of death. The body was that of a well-developed, well-nourished, muscular young man. The skin, particularly of the face, had a lemon tint, and the lips were cyanosed. The amputation site in the upper third of the right arm showed patches of yellowish-white necrotic muscle, the largest being 2 × 1 × 1 cm., with definite margins, and homogeneous on section except in one place which retained the lobulation of muscle compartments. A few small hæmorrhages, up to 0·3 cm. in diameter, bordered the necrotic patches. Otherwise the muscle surfaces of the stump appeared slightly dry but normal in colour and clean. Several patches of similar necrosis, up to 3 cm. in diameter, were present in both external oblique muscles. There was also a core of necrosis running longitudinally through the posterior part of the inferior half of the left psoas, alongside and partly enwrapped by a long hæmorrhage with crescentic cross-section up to 0·8 cm. thick—the hæmorrhage and adjacent necrosis thus forming a cylindrical zone in the interior of that part of the psoas lying over the pelvic brim. There was œdema of the skeletal muscles as of the tissues generally, and the neck muscles dripped fluid on section. No necrotic or hæmorrhagic areas were seen in sternomastoids, pectorals, recti abdominis, biceps or brachialis (left), quadriceps group (right), temporal muscles, or deltoid above amputation.

There was œdematous enlargement of cervical lymph-nodes, and an adhesion between the faucial pillars on the left side, the tonsils being absent. There was much froth in the trachea and the lungs dripped œdema on section and showed congestion of the lower lobes, but no pneumonia. Fibrous pleural adhesions were present over the left upper lobe. There were bilateral pleural effusions (4 oz. left, 12 oz. right) and slight excess of dark yellow pericardial fluid. Four ecchymoses, up to 0·25 cm. in diameter, marked the course of the coronary vessels over the left ventricle; the coronary arteries were clean and patent. There were two slight puckered depressions in the lining of the aorta just distal to the valve, each about 0·3 cm. in diameter: they were not due to atheroma, which was slight throughout the body. The heart muscle was very œdematous and the pulmonary arteries and great veins, including splenic, renals, and iliacs, were dilated by post-mortem clot. There was œdema and congestion of intestines, liver, small spleen, pancreas, and brain (excepting in the frontal lobes, which were pallid). A venous infarct, 0·2 cm. in diameter, was present in the cortex of the right suprarenal. The kidneys were swollen, with bulging cut-surfaces and great congestion and œdema of both cortex and medulla. The bladder was distended by about one pint of clear urine. A sample of serum gave a negative Kahn test and *Cl. welchii* was grown from various muscles.

Micropathology.—Sections of the affected parts of the voluntary muscles showed, like those of case 1, granular and hæmatoxyphil degeneration without exudate but with occasional intravascular collections of inflammatory cells. Sections of the kidney showed the changes described in case 1 with three differences: the cortical (including the glomerular) vessels were congested as well as those of the medulla; lymphocytic foci were absent; and a little free iron pigment was demonstrated. The brain-stem showed several small vessels packed with subacute inflammatory cells and polymorphs which had not infiltrated the parenchyma; one suprarenal had a venous infarct; the lungs showed congestion and œdema with much desquamation of epithelium and albuminous exudate in some alveoli; the liver, œdema, uniform congestion, and fatty degeneration; the spleen, a distinct septic reaction; a cervical lymph-node showed reactive hyperplasia. Gram's stain failed to show organisms in any tissue.

DISCUSSION

On the hypothesis of a common ætiology, various types of renal failure, formerly considered separate, are now being associated in one group. Such lists are furnished by Bywaters (1945), suggesting functional renal blockage as the common factor; by Maegraith et al. (1945), suggesting renal anoxia; and by Trueta et al. (1947) suggesting cortical anoxia due to an autonomically controlled vascular cut-out. The kidney of this syndrome is usually described as swollen, with pale œdematous cortex, congested medulla, tubular degeneration, eosinophil capsular exudate, normal tufts, and a variable number of casts. It has not been found possible to prove any ætiology from these changes.

Ischæmic muscle patches at sites distant from those of direct violence should strengthen the case for a spasmodically induced renal ischæmia; but no other cases seem to have been reported. Arterial spasm has often been seen by surgeons in cases of hæmorrhage (Malcolm 1893, Handler 1949); but at the symposium on crush-syndrome cases at the Royal Society of Medicine (1941) no cases were reported of necroses unassociated with local trauma to muscle or blood-vessel; nor do necroses seem to have been previously recorded (apart from local vascular damage) in cases of post-traumatic uræmia. The deaths of these two soldiers are reported because they display this phenomenon. Every possible surviving detail has been collected; but the specimens and most of the notes were lost by misfortune of war.

The sequence of events was no different from that often previously described (e.g., Darmady et al. 1944)—namely, exsanguination, resuscitation, surgery, recovery, causeless deterioration (fifth day) with subnormal temperature and pulse but normal blood-pressure and urine, azotæmia, death (tenth day), inconclusive necropsy with near-normal kidneys showing tubular degeneration histologically. The description given by Bywaters (1944) of the muscular necroses in crush-syndrome applies accurately to these two cases, where there was no crush injury; the patches were friable, opaque, sometimes

RENAL DYSPLASIA IN A FAMILY WITH MULTIPLE HEREDITARY ABNORMALITIES INCLUDING ILIAC HORNS *

With illustrations on plate

RECORDS of families suffering from a condition indistinguishable from chronic nephritis have been published occasionally since the beginning of this century. There is little doubt that this condition is hereditary and familial, for often several successive generations of a family are affected; but opinion has differed on whether there is a "weakness" of the kidneys predisposing to postnatal infection or whether the abnormality is in fact congenital.

Unlike those previously reported, the family I have studied presents a number of associated anomalies, whose congenital nature is indisputable. The association suggests that the renal lesion is also an inherited developmental anomaly.

PREVIOUS RECORDS

Dickinson (1875) mentioned a family of three generations suffering from albuminuria, and Guthrie (1902) described a family where 12 persons out of 15 suffered from hæmaturia with recurrent back pains and pyrexia. Their urine showed a permanent albuminuria with blood casts and a specific gravity of 1015–1030. As he observed neither œdema nor cardiovascular change, he ascribed these findings to weakness of the blood-vessels of the kidney. Hurst (1923) followed up the same family over ten years. He finally reported that 4 out of 8 members were affected in one generation, 8 out of 12 in the next, and 5 out of 8 in the third. Many of the family showed a typical nephritis with albuminuria, hæmaturia, and casts of all types, developing cardiac hypertrophy and dying from uræmia. Hurst called the disease hereditary because three generations were affected, familial because several members of one family were concerned, and congenital because in one instance abnormal urine was found in a child three weeks old, in another at two years, and otherwise in early childhood.

Descriptions by other writers have confirmed Hurst's views. Aitken (1909) mentioned a father dying from uræmia, 2 of whose children had hæmaturia during the first weeks of life. In 3 others, blood was seen in the urine at twelve to eighteen months and another had microscopical hæmaturia at eleven months. One died from uræmia at three years. He, too, emphasised periodic febrile attacks associated with anæmia. Similar records are given by Attlee (1901), Osman (1927), and others. In 1924 Eason et al. reviewed the subject as well as discussing two families of their own. They suggested that there was an intrinsic weakness, or *locus minoris resistentiæ*, in the kidney, and that a possible extrinsic factor in the recurrent attacks was a streptococcal infection. There is no denying that family vulnerability to a common infecting organism may explain some instances, but it hardly seems to account for the occurrence of the disease in successive generations.

The ætiology of this so-called familial nephritis is not clarified by histological study of the kidneys; for according to Osman (1949) there may be nothing to distinguish it from acquired chronic glomerular nephritis.

It may be relevant to note that Herxheimer (1908), when studying the kidneys of infants, found minute foci with increased connective tissue and atrophic urinary tubules, which, since there were no inflammatory changes, he attributed to an error in development, classing them with the hyaline glomeruli and small cysts common in kidneys of infants. Nicholson (1931) mentioned similar structures in an embryonic kidney tumour from a stillborn fœtus, and attributed them to a local arrest of the formation of collecting tubules and metanephric vesicles. Possibly a similar though more extensive failure of development may be responsible for the condition now being discussed.

THE FAMILY

The Y family first came under observation because of their rare skeletal abnormalities, including iliac horns, which have hitherto received scant attention in the literature and have not been demonstrated as familial and hereditary.

Originating in a district which, far from being isolated, was open to the sea-routes of the world, the family had dispersed widely, as the brothers of the third generation sought employment elsewhere and brought up their own children under quite different environmental conditions. They were all of normal mental and physical development and not handicapped by their abnormalities. There was no history of consanguinity. In all, 36 members were traced or observed, and developmental anomalies of some kind were discovered in 21. Most of the latter were examined personally and no diagnosis of bony change was made except on radiological evidence. It was in the course of this study that 4 members (fig. 1) were found to be suffering from a renal lesion similar to chronic glomerular nephritis.

CASE-REPORTS

Case 1 (no. III 1).—John Y, aged 45 years, was a thin, pale, asthenic man who complained of frequency of micturition for some years but was otherwise well, apart from vague back pains, related to posture and probably originating from deformity of his spine. He was able to do heavy manual work, and there was no change in his condition during observation over three years. His previous health had been satisfactory: there was no history of renal disorder, but he had always been liable to frequent colds, nasal catarrh, and respiratory infections. He stated that his mother, who had died at the

---

* Communicated to the Association of Physicians, June, 1949.

The signs and symptoms referable to the right arm were so pronounced that a diagnosis of embolism, probably from an aortic plaque, seemed obvious, and the pain in the chest (which was diminishing) was ascribed to a coronary thrombosis. Treatment with heparin and papaverine was started, and with caution 200 mg. of tetra-ethyl-ammonium bromide was given. On this régime the circulation in the arm began to improve; after 6 hours the radial pulse was just palpable and sensation and muscle power were returning. Later, the patient became very restless, and his pulse-rate began to rise. At 11.30 P.M. auricular fibrillation appeared, and the patient lost consciousness. *He died at 1.20 A.M.*

At necropsy, by Dr. E. A. Horne, the pericardium contained $^{1}/_{2}$ pint of recent blood-clot from rupture of the aorta. There was marked hypertensive hypertrophy of the left ventricle; the valves were normal.

Varying from 1·5 to 2 cm. above the aortic ring, there was a large irregular transverse tear of the intima, about 5 cm. in length, leading into a dissecting aneurysm of the thoracic aorta. There was some atheroma present (figs. 1 and 2). The innominate and carotid arteries and the right brachial and axillary arteries were dissected out and all found to be involved. In the artery to the right arm, the aneurysm stopped abruptly at the junction of the brachial and axillary artery, re-entering the vessel at this point. A cross-section of the vessel here showed almost complete obliteration of the lumen of the vessel by the inward displacement of the intima by blood (fig. 3).

The lungs showed acute pulmonary œdema.

DISCUSSION

The clinical picture produced by a dissecting aneurysm involving peripheral vessels is fairly clear cut, differing in several respects from that produced by an embolus.

Pain is of sudden onset, in the chest, back or abdomen, and is immediately maximal, causing much shock. It is due to the splitting of the aortic wall, and rupture of intercostal and lumbar arteries, and radiates or spreads into the limbs or up into the neck, depending on the course of the dissection. Embolism, on the other hand, is not necessarily associated with pain. Allen et al. (1946) state that in only 48% of cases of embolism are symptoms immediate, and when pain does occur it is usually confined to the limb involved.

In case 1 there was no clear history of pain at the commencement of the illness, but the dissection may have interfered with the blood-supply of the brain, causing loss of consciousness, and thus masking the pain.

Obliteration of Pulses.—Associated with the pain, after an interval, are the symptoms and signs of vascular occlusion, usually in the legs, but also in the viscera and brain (White 1947). There may only be a weakening of the pulse in the limb, or there may be evidence of complete arterial occlusion. This is due to the blood dissecting in the media and pressing the intima inwards. Half to three-quarters of the circumference of the vessel may be involved, and the intima displaced 0·5 to 1 cm. Vascular spasm adds to the effect of the encroachment on the lumen (fig. 3).

Associated Diseases.—Two factors are almost always associated with the production of a dissecting aneurysm —areas of medial necrosis of unknown origin, and hypertension. Atherosclerosis and syphilis as a cause are rare. The dissection is commonly initiated by a sudden strain.

Embolism usually occurs in a patient who has some obvious source for an embolus, such as mitral stenosis or auricular fibrillation, though thrombi may form on atheromatous plaques on the aorta. A dissecting aneurysm strikes down a previously healthy man, while the victim of an embolus is often in poor health. Coronary thrombosis as a cause of the pain in the chest can be excluded by the absence of the typical electrocardiographic changes.

Abnormal sounds on auscultation may give a useful lead in some cases, though in others they may be absent. Thus in case 1 the strong basal cardiac thrill should have caused us to pause and reconsider, had we not from the outset accepted the diagnosis of embolism without question. In this case the correct diagnosis was not made by us even after operation; though we were in possession of facts irresistibly pointing to the lesion, we failed from sheer ignorance to draw the proper conclusion. Subsequently, however, we have been able to diagnose abdominal aortic dissecting aneurysm masquerading as "acute surgical abdominal disease" simply from the presence of a rough murmur on auscultation.

Treatment.—It appears that when the dissection has spread to involve peripheral arteries, death follows quickly. In none of the cases which survive more than a few days is there any mention of symptoms of vascular occlusion.

The cause of death is usually rupture of the aorta into the pericardium or mediastinum, and the only treatment is absolute rest, but every effort should be made to overcome the vascular spasm present when the dissection reaches the peripheral arteries, which must contribute to the occlusion and add to the shock. Relaxation of the spasm may allow enough blood to flow into the limb to maintain its nutrition; the collateral circulation is uncertain because the origin of the vessels taking part in the anastomosis may be involved in the dissection.

Gurin et al. (1935) reported a case in which incision of the intima to allow the blood to re-enter the lumen of the vessel relieved the vascular obstruction sufficiently for the nutrition of the limb to be maintained until the patient's death six days later, but the chances of performing this operation must be rare indeed.

The modern trend in the treatment of emboli is to rely on the early application of conservative measures, with embolectomy held in reserve for the cases which do not quickly respond (Allen et al. 1946). These measures can have little adverse effect on the outcome of a dissecting aneurysm, but the result of failing to treat an embolus is disastrous, and so all cases of vascular occlusion, whatever the diagnosis, should immediately be started on conservative treatment. It is possible to diagnose an embolus as a dissecting aneurysm (Massachusetts General Hospital 1936).

The limb should be lightly covered and kept in a horizontal or very slightly dependent position, according to the presence or otherwise of œdema, at room-temperature. Opiates should be given for the pain, papaverine and/or tetra-ethyl-ammonium bromide to relieve vasospasm, and heparin to prevent intravascular thrombosis. A sympathetic block is a valuable addition to therapy. In case 2 these measures appeared definitely to benefit the circulation of the arm, and had the case been one of embolism, the limb would probably have regained normal function.

We are indebted to Mr. F. C. Hunt, under whose care these cases were admitted, for permission to publish them, to Dr. E. A. Horne for post-mortem examinations and much other valuable help, and to Mr. E. S. McLeod, M.S.R., C.T., for the photographs.

RECORDS of families suffering from a condition indistinguishable from chronic nephritis have been published occasionally since the beginning of this century. There is little doubt that this condition is hereditary and familial, for often several successive generations of a family are affected; but opinion has differed on whether there is a "weakness" of the kidneys predisposing to postnatal infection or whether the abnormality is in fact congenital.

Unlike those previously reported, the family I have studied presents a number of associated anomalies, whose congenital nature is indisputable. The association suggests that the renal lesion is also an inherited developmental anomaly.

PREVIOUS RECORDS

Dickinson (1875) mentioned a family of three generations suffering from albuminuria, and Guthrie (1902) described a family where 12 persons out of 15 suffered from hæmaturia with recurrent back pains and pyrexia. Their urine showed a permanent albuminuria with blood casts and a specific gravity of 1015–1030. As he observed neither œdema nor cardiovascular change, he ascribed these findings to weakness of the blood-vessels of the kidney. Hurst (1923) followed up the same family over ten years. He finally reported that 4 out of 8 members were affected in one generation, 8 out of 12 in the next, and 5 out of 8 in the third. Many of the family showed a typical nephritis with albuminuria, hæmaturia, and casts of all types, developing cardiac hypertrophy and dying from uræmia. Hurst called the disease hereditary because three generations were affected, familial because several members of one family were concerned, and congenital because in one instance abnormal urine was found in a child three weeks old, in another at two years, and otherwise in early childhood.

Descriptions by other writers have confirmed Hurst's views. Aitken (1909) mentioned a father dying from uræmia, 2 of whose children had hæmaturia during the first weeks of life. In 3 others, blood was seen in the urine at twelve to eighteen months and another had microscopical hæmaturia at eleven months. One died from uræmia at three years. He, too, emphasised periodic febrile attacks associated with anæmia. Similar records are given by Attlee (1901), Osman (1927), and others. In 1924 Eason et al. reviewed the subject as well as discussing two families of their own. They suggested that there was an intrinsic weakness, or *locus minoris resistentiæ*, in the kidney, and that a possible extrinsic factor in the recurrent attacks was a streptococcal infection. There is no denying that family vulnerability to a common infecting organism may explain some instances, but it hardly seems to account for the occurrence of the disease in successive generations.

The ætiology of this so-called familial nephritis is not clarified by histological study of the kidneys; for according to Osman (1949) there may be nothing to distinguish it from acquired chronic glomerular nephritis.

It may be relevant to note that Herxheimer (1908), when studying the kidneys of infants, found minute foci with increased connective tissue and atrophic urinary tubules, which, since there were no inflammatory changes, he attributed to an error in development, classing them with the hyaline glomeruli and small cysts common in kidneys of infants. Nicholson (1931) mentioned similar structures in an embryonic kidney tumour from a stillborn fœtus, and attributed them to a local arrest of the formation of collecting tubules and metanephric vesicles. Possibly a similar though more extensive failure of development may be responsible for the condition now being discussed.

THE FAMILY

The Y family first came under observation because of their rare skeletal abnormalities, including iliac horns, which have hitherto received scant attention in the literature and have not been demonstrated as familial and hereditary.

Originating in a district which, far from being isolated, was open to the sea-routes of the world, the family had dispersed widely, as the brothers of the third generation sought employment elsewhere and brought up their own children under quite different environmental conditions. They were all of normal mental and physical development and not handicapped by their abnormalities. There was no history of consanguinity. In all, 36 members were traced or observed, and developmental anomalies of some kind were discovered in 21. Most of the latter were examined personally and no diagnosis of bony change was made except on radiological evidence. It was in the course of this study that 4 members (fig. 1) were found to be suffering from a renal lesion similar to chronic glomerular nephritis.

CASE-REPORTS

Case 1 (no. III 1).—John Y, aged 45 years, was a thin, pale, asthenic man who complained of frequency of micturition for some years but was otherwise well, apart from vague back pains, related to posture and probably originating from deformity of his spine. He was able to do heavy manual work, and there was no change in his condition during observation over three years. His previous health had been satisfactory: there was no history of renal disorder, but he had always been liable to frequent colds, nasal catarrh, and respiratory infections. He stated that his mother, who had died at the

* Communicated to the Association of Physicians, June, 1949.

Nine members of the Y family were found to have these structures, and in each case the triad affecting the fingernails, elbow-joints, and patellæ was present as well. Unsuspected by their owners, the processes, if well developed, formed a slight visible elevation in the smooth contour of the buttock, and could otherwise be easily palpated beneath the gluteal muscles, about 8 cm. below the iliac crests and between 5 and 14 cm. from the midline according to their length. The larger ones (figs. 6 and 7) were striking features on the radiograph, whereas the rudimentary "horns" presented as a small but characteristic pattern in the centre of the ilium (fig. 8), a feature that could easily be missed unless attention was directed to the possibility of their presence. They were easily visible on the radiograph of a boy aged 9 months, and terminal epiphyses were seen on the iliac horns of a girl, aged 14 years (fig. 9).

One is impressed by the apparently purposeful nature of these structures, which are symmetrical and well shaped, unlike the irregular projections of exostoses. Stereoscopic radiography confirms their continuity with the iliac bones, with trabeculæ woven into them. The remark of Sir James Paget about congenital abnormalities is applicable; he said that "we ought not to set them aside with idle thoughts or idle words about 'curiosities' or 'chances.' Not one of them is without meaning; not one that might not become the beginning of excellent knowledge, if only we could answer the question —why is this rare? Or being rare, why did it in this instance occur?" (Paget 1882). However, ignorance concerning the mutational disorders has changed little since these words were spoken, and knowledge of the physiology and growth of bone is still slight.

MEMBERS OF THE Y FAMILY

Generation	No.	Sex	Age	History	Physical Examination *	Urine	Radiology
I	1	M	Dead	Died of old age. Said to have inherited the family triad (fingernails, elbows, patellæ) from previous generations	..	..	..
II	1	F	Dead	Died of dropsy at 64. Said to have the family triad	..	..	..
	2	M	Dead	Said to have the family triad	..	..	..
III	1	M	45	Case 1	Multiple angiomata. Pigeon-chest. Family triad. Palpable iliac horns. Thoracic kyphosis	Albumin + +. Casts of all types. Occasional red cells	Arthrodysplasia both elbows. Rudimentary patellæ. Iliac horns.† Spina bifida at *C6, 7, D1, 2, 3*. Long transverse processes C7. *Calcified disc at D10–11*
	2	M	42	Case 3	Multiple angiomata. Pigeon-chest. Family triad. Palpable iliac horns. Congenital cataract	Albumin + +. Casts of all types. Occasional red cells	Arthrodysplasia both elbows. Rudimentary patellæ. Iliac horns (small). Spina bifida C7, T1. Long transverse processes C7
	3	M	38	Rather frail. Rejected by the Army on physique	Hemidysplastic thumbnails; fingernails normal. Elbows: extension limited by 10° and supination by 40°. Patellæ small. Palpable iliac horns. Thoracic kyphosis. Short hamstrings. Lumbar spine stiff. Pes planus. Right pupil larger than left, but reactions normal; no other sign of organic disease. B.P. 155/95	Normal	Arthrodysplasia of elbows. Iliac horns. No spina bifida. Lumbar spine shows ankylosing spondylitis
	4	M	36	The most healthy man in this generation, showing excellent muscular development	Thumbnails show longitudinal split. Elbow changes moderate. Otherwise normal	Norma	Arthrodysplasia of both elbows. Both patellæ small. No spina bifida. No iliac horns
	5	M	35	Served in Regular Army, but had had a perforated duodenal ulcer and pulmonary tuberculosis	Thumbnails only were hemidysplastic. Elbows: pronation limited to 50°. Patellæ absent. Occasional angiomata on skin. Palpable iliac horns 8 cm. below iliac crest and 12 cm. from midline	Normal	Moderate degree of arthrodysplasia. Iliac horns, right larger than left (about 1 × 2 cm. on antero-posterior film). Spina bifida at C4, 5, 6, 7, T1. Long transverse processes at C7
	6	M	33	Healthy. Manual labourer	Left elbow: extension limited by 30°; flexion normal; pronation limited by 60°. Right elbow: extension limited by 10°; flexion normal; pronation limited by 50°. Left thumbnail almost absent; right thumbnail a small ridge at base of nail-bed. Fingernails normal. Patellæ just palpable. Occasional angiomata on skin. Thoracic scoliosis	Normal	Severe degree of arthrodysplasia of elbow-joints. Spina bifida at C4, 5, 6, 7. Long transverse processes at C7
	7	M	Dead	..	Born with family triad and also polydactyly. Died in infancy from hæmorrhage after removal of supernumerary little fingers	..	..
	8	F	39	Healthy, married with no family	Dysplasia of thumb and first fingernails. Elbows and patellæ almost normal	Normal	Slight arthrodysplasia of elbows. Iliac horns (rudimentary). Spina bifida at C6, D1 and 2. Long transverse processes at C7

Iliac horns might be an atavistic feature, but Fraser (1948) could not trace their occurrence in other mammals. They may be analogous to lumbar or sacral ribs. There is certainly no evidence to suggest their acting as muscle insertions, and anatomists such as Johnston (1948) think this unlikely. Apparently the most that can be said at present is that they are a rare mutational abnormality.

Genetic Aspect

The incidence of the various abnormalities found in the 36 members of the Y family who were traced was as follows:

The family triad:	
Dysplasia of fingernails Arthrodysplasia of elbow-joints Rudimentary patellæ	18
Iliac horns	9
Renal dysplasia	6
Cervical spina bifida with long transverse processes of C7	5
Cervical ribs	3
Angiomatosis of skin	3
Pigeon-chest	2
Thoracic kyphosis	2
Congenital cataract	3

The facts are set out more fully in the accompanying table, and illustrated in figs. 1–3.

There is no doubt that the commonest syndrome, the triad affecting the fingernails, elbow-joints, and patellæ —is the result of a simple heterozygous dominant gene. The occurrence of this in the third generation might suggest a sex linkage, and the incidence by chance in the sexes is on the borderline of probability, as $\chi^2 = 5{\cdot}84$ ($P = 0{\cdot}05$). However, the impression of a sex-incidence is probably due to the greater number of brothers born: in other words, it is probably incidental, for there is no known sex-linkage which could have affected *no.* II 1 (female) and come through her to the seven males of the third generation.

With one doubtful exception (III 10) the instances of iliac horns, renal dysplasia, pigeon-chest, cutaneous

3rd. METACARPAL
LONGITUDINAL DIAGONAL approx. length 2¼ in.
CARPUS
RADIUS
TRANSVERSE DIAGONAL approx. length ¾ in.

Fig. 2—Diagram to show measurements of bed.

The bone enclosed within the diamond-shaped cut is removed by a small gouge: it includes the posterior half of almost the whole width of the lower radial articular surface and the greater part of the articular surfaces of the scaphoid, semilunar, and os magnum. The length and breadth of the diamond-shaped bed are now measured, and a graft is cut from the lower part of the medial surface of the tibia of a size to fit tightly into it. This is not difficult: the area is defined by marking out on the bone the transverse and longitudinal diagonals of the diamond so that they bisect each other at right-angles, and joining their extremities (fig. 3). If the graft is cut from the appropriate part of the tibia, its cortical surface will be concave and its cancellous surface convex (figs. 4 and 5). It should be so cut that its greatest width corresponds to the summit of the convexity.

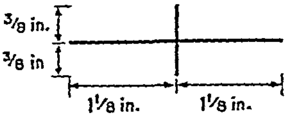

Fig. 3—Diagram to show measurements of graft.

The graft is now transferred to the wrist and punched into the bed already made for it, the proximal pointed angle being slotted under the cortical surface of the upper corner of the bed, and (traction being applied to the wrist) the lower pointed angle slotted into the third metacarpal in the manner used for Brittain's arthrodesis. It is not necessary to cut steps in the proximal and distal angles of the graft: cutting steps in the ends of a graft always weakens it. If the graft is made with pointed ends, and so can be slotted into the metacarpal and radius, the necessity for steps is avoided. With this method, in contrast to Brittain's, the graft is laid with its cancellous surface downwards and not directed to the radial or ulnar sides. I believe that any drawbacks to placing the graft in such a way are offset by the fact that the maximum width of the graft corresponds to the site of the maximum strain, and that the actual width of the graft at this site is much greater than the width of Brittain's graft. When the graft is being fitted the wrist must be put in a position of dorsiflexion neither too little nor too great; and if the long axis of the graft is made to run truly from the central axis of the radius to the base of the third metacarpal there will be neither undue radial nor undue ulnar deviation. Cancellous-bone chips taken from the donor area are packed around the graft. After the extensor retinaculum has been sutured and the wound closed, the wrist is immobilised in plaster for at least two months (fig. 6).

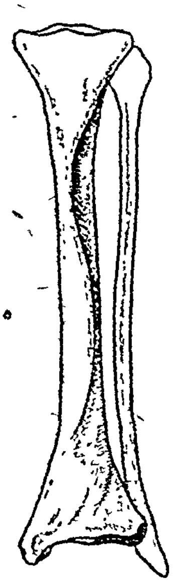

Fig. 4—The lower part of the medial surface of the tibia is concave forwards. A graft can be cut from this portion to fit the dorsiflexed wrist. Furthermore, removing the graft from this portion of the tibia makes cancellous bone chips available.

ADVANTAGES

1. Union is promoted because the greatest amount of bone is removed at the level of the joint; the greatest width of the graft is at joint level; cancellous-bone is used as well as cortical bone; and fixation is secure.

2. Stable fixation is achieved by fixing the graft at both ends by means of the method of slotting; using the inlay method when applying the graft, and having the greatest width of the graft at the site of the greatest possible movement (i.e., at the radio-carpal joint level). As the shape of the graft naturally fits dorsiflexion of the wrist, no attempt is made to strain the graft out of its normal shape (fig. 5). Being curved, the graft fits down into the bed throughout its length.

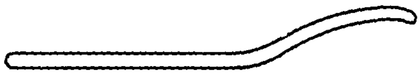

Fig. 5—Graft in profile.

3. No bulky mass is laid on the back of the radius and carpal bones. The extensor tendons will lie back evenly in place because the bony contour is little altered —except of course, that Liston's tubercle is removed when the graft bed is excised.

4. The movements of pronation and supination are preserved. In dealing with a joint in which these movements are already destroyed the lower end of the ulna can be removed in the course of operation with a view to restoring them.

I wish to thank Miss Jean Evison for her help with the illustrations and preparation of this article.

BASILAR INVAGINATION IN PAGET'S DISEASE

R. A. Goodbody
M.B. Lond.
REGISTRAR IN PATHOLOGY, LEWISHAM GROUP LABORATORY

L. V. Roberts
M.D. Edin.
PHYSICIAN, LEWISHAM HOSPITAL

With illustration on plate

Basilar invagination (*syn.* basilar impression, platybasia) is a rare craniovertebral deformity due to the foramen magnum and surrounding bone being pushed up into the posterior fossa by the atlas. The upper cervical vertebræ are thus displaced upwards, and usually forwards. In the majority of cases a congenital developmental anomaly of the basi-occiput, atlas, and axis is responsible; in the remainder the condition is almost always the result of Paget's disease. Neurological symptoms are common in the congenital but rare in the acquired type. They are significant of pressure on: (1) the hind brain and lower cranial nerves by the invaginated bone, accentuated by the correspondingly smaller posterior fossa; (2) the medulla and upper cervical cord by a narrowed foramen magnum, and distorted upper cervical canal, aggravated perhaps by the frequent, usually unequal, herniation into them of the cerebellar tonsils. Syndromes produced may simulate syringomyelia, disseminated sclerosis, tumour of the posterior fossa, motor neurone disease, and other disorders. Internal hydrocephalus is likely to complicate the severer degrees of deformity.

In only one of the cases secondary to Paget's disease so far published has involvement of the central nervous system been noted (Ray 1942). A second case is reported here.

CASE-RECORD

The patient, an obese woman of 56, was brought to hospita late one evening in a state of coma.

History.—She had developed during the preceding fortnight an unusual habit of dozing in her chair of an evening. On the previous afternoon she had fallen deeply asleep and could not angiomata, and spinal deformities all occur in members of the family bearing the characteristic triad. Congenital cataract, appearing in the eldest of the seven brothers (III 2), affects his two daughters (IV 5 and 7) who are otherwise normal; it may appear by chance, and will not be included further in the discussion of the main abnormalities.

Two explanations of the Y pedigree then seem possible.

1. That the numerous and diverse congenital anomalies are due to the action of a single, rather versatile gene, which shows variations in penetrance for particular characteristics.
2. By analogy with the recent theories concerning the blood-group genes (Fisher 1949), it is possible that several genes, closely associated on the same chromosome, may be responsible. These loci may be so near together that crossing-over hardly ever occurs and they act as a unit in inheritance.

CONCLUSION

A type of renal dysplasia is described which presents the same clinical picture as chronic glomerular nephritis. Thus there is persistent albuminuria with casts of all types and occasional red blood-cells. Renal function is slightly diminished and radiography shows kidney shadows of normal size and shape. A 'Uroselectan' (iodoxyl) study excludes polycystic disease. Four definite cases are recorded and two probable ones, both the latter having died with generalised œdema.

This form of dysplasia may account for the so-called familial congenital nephritis described by previous writers. When such families are discovered in future a careful search may reveal other hereditary anomalies. No opportunity has arisen in the present family for detailed pathological study; but, if the analogy with congenital nephritis is correct, there is probably nothing to distinguish the final picture from acquired chronic glomerular nephritis. The course of this developmental renal lesion may, however, be more benign than the acquired disease. The general condition of the patients was good and hypertension was found in only one. A child aged 8 years showed normal physical development with no sign of renal rickets. The oldest living person was 45, and the two thought to have died from the condition lived to 64 and 47 years.

The Y family also possess a great number of congenital abnormalities affecting tissues both of ectodermal and mesodermal origin. The commonest trait involves *the fingernails, elbow-joints, and patellæ and is known* by the family to have been inherited from distant ancestors.

Many who have this triad also show other changes affecting the skin, vertebral column, and pelvis. A particular study has been made of iliac horns, because these have hitherto had scant attention and have not been demonstrated as a hereditary characteristic. It is thought that the detailed analysis of so many widely scattered developmental errors may in the distant future be of some value in preparing a map of the human chromosome.

I am very grateful to Dr. F. Parkes Weber for his enthusiastic encouragement, and also to Prof. Lancelot Hogben, F.R.S., and Dr. A. A. Osman for their helpful advice. Acknowledgment is made to Dr. Harold Black for permission to reproduce the radiographs; and the investigation would not have been possible without the ready coöperation of Sister Le Gallais and the staff of the X-ray department. Grateful appreciation is expressed to Dr. A. A. Cunningham and Dr. Ian MacCallum for help with cases in their area, and I would like to thank Prof. P. C. P. Cloake for permission to study the original case which was discovered in his outpatient department.

I am indebted to the Medical Research Council for a grant to cover the expenses of this work.

A METHOD OF
ARTHRODESIS OF THE WRIST

DAVID F. THOMAS
F.R.C.S.
ORTHOPÆDIC SURGEON, SCUNTHORPE AND DISTRICT
WAR MEMORIAL HOSPITAL AND LINDSEY COUNTY COUNCIL

With illustration on plate

THE operation described here has been designed to promote a more certain arthrodesis of the wrist in a good position than is generally achieved. It has advantages over the usual methods, and consists essentially in fusion of the joint by a diamond-shaped inlay graft.

THE METHOD

A posterior, midline incision is made from the base of the third metacarpal to a point about 2 in. proximal to the lower end of the radius. The extensor retinaculum is divided and reflected on each side, and the extensor tendons are separated between the extensor digitorum communis on the one hand and the extensor proprius indicis and longus pollicis on the other hand. The whole of the posterior surface of the lower 2 in. of the radius is cleaned, and the posterior surfaces of the semilunar, scaphoid, and os magnum, as well as the base of the third metacarpal, are also cleaned. A diamond-shaped bed is now cut (fig. 1). The wrist must be in moderate dorsiflexion when this is done. The most distal corner of the bed includes the base of the third metacarpal. The most proximal corner is the same distance from the lower margin of the radius as this margin is from the base of the third metacarpal; and the line joining the distal and proximal angles should bisect the line joining the medial and lateral angles (fig. 2). The medial angle is just lateral to the medial angle of the lower end of the radius and the outer angle a little medial to the tip of the styloid process of the radius. The saw-cut is about $^3/_8$ in. deep throughout its extent.

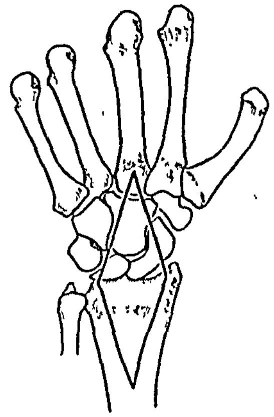

Fig. 1—The diamond-shaped bed is cut from the lower part of the radius, the greater part of the semilunar, scaphoid, and os magnum, and from the base of the third metacarpal bones. Both apices of the bed are tunnelled so as to allow for slotting of the graft after the manner of Brittain's operation. At the medial angle of the diamond care is taken to avoid encroaching on the inferior radio-ulnar joint.

gait—the identical earliest symptoms manifested by Ray's patient. Secondly, the Paget skull and the shortened neck. And thirdly, the signs of increased intracranial pressure—papillœdema and coma (preceded by hypersomnia), later shown to be due to internal hydrocephalus of the communicating type. The hydrocephalus was undoubtedly caused by obstruction of the subarachnoid space at the incisura tentorii, and must have been present for some time to produce such advanced changes in the pituitary fossa. The sudden coma may have coincided with development of cerebellar tonsillar herniation but more probably signified that the hydrocephalus had attained a degree which the diseased skull was incapable of accommodating. Radiological findings were characteristic; they are the only certain means of diagnosis during life.

We do not think that lumbar puncture or mastoidectomy appreciably affected the fatal issue. The latter operation proved that the deafness, a common symptom in uncomplicated Paget's disease, was largely due to destruction of the ossicles by the disease process. Suboccipital decompression would have eased pressure on the hind brain, and might even have saved the patient's life.

SUMMARY

A rare case of acquired basilar invagination with involvement of the central nervous system, due to Paget's disease, is reported. A unique feature was the development of internal hydrocephalus and coma leading to a fatal termination.

MEDICAL ASPECTS OF CARCINOMA OF THE PROSTATE WITH SECONDARY DEPOSITS IN BONE

M. H. OELBAUM
M.B., B.Sc. Manc., M.R.C.P.
MEDICAL CHIEF ASSISTANT, MANCHESTER ROYAL INFIRMARY

With illustrations on plate

THE discovery that œstrogens can be used efficiently in the treatment of prostatic carcinoma has made early and correct diagnosis of great importance. Carcinoma of the prostate may be indistinguishable clinically from simple hypertrophy, even though it may already have given rise to metastases. It is therefore very fortunate that a biochemical test—the estimation of acid phosphatase in the serum—has proved of such value in diagnosis, especially when there are osseous metastases.

DEVELOPMENT OF THE TEST

Slight increases in the serum acid phosphatase have been recorded in various non-prostatic conditions, one of the most important of which is Paget's disease of bone. This is especially to be noted, because great difficulty may be experienced in differentiating between the radiological pictures of osteoplastic metastases in the pelvis and Paget's disease. If the serum acid phosphatase is found to be very high, then there is no doubt of its significance; but if it is only slightly raised (5–10 units) then Paget's disease is not excluded (Watkinson et al. 1944, Herbert 1946).

A notable advance was made by Herbert (1944, 1945) when she demonstrated that prostatic acid phosphatase in serum is destroyed by alcohol but that acid phosphatase in normal serum (produce by extraprostatic tissues) is alcohol-stable. Thus the moderate increase in serum acid phosphatase sometimes found in Paget's disease is all alcohol-stable, whereas in metastasising prostatic carcinoma, with raised serum acid phosphatase, treatment of the serum with alcohol lowers the titre usually to normal. Occasionally even when the total serum acid phosphatase titre is not raised a significant amount of prostatic phosphatase in the serum may enable a diagnosis of prostatic carcinoma to be made. Thus out of 29 cases of prostatic carcinoma in which the total acid phosphatase was normal there was a significant fall in titre in 5 cases after alcohol treatment (Herbert 1946). In normals the drop in acid phosphatase when the serum is treated with alcohol should not be more than 1 unit, and if a suspicious fall is encountered a repetition of the test will settle the point. From Herbert's series also it can be seen that the diagnostic value of the test is limited to some extent by the fact that prostatic phosphatase is not always found in the serum in prostatic carcinoma, though it is nearly always present when there are metastases in bone. Later, Herbert (1946) found the serum acid phosphatase raised in 29 out of 35 cases of prostatic carcinoma with bone metastases; but only 12 out of 47 showed an increase in titre when there was no evidence of metastases radiologically. There is little doubt that in these 12 patients chemical evidence of metastatic spread anticipated X-ray demonstration.

LEUCO-ERYTHROBLASTIC ANÆMIA

This is a term used for an anæmia characterised by the presence in the peripheral blood of immature red cells and a few immature white cells of the myeloid series. Vaughan (1936) studied 13 patients with such an anæmia and found that carcinomatosis was the cause in 8 cases. Other conditions which have been responsible are marble-bone disease of Albers-Schönberg, myelosclerosis, multiple myelomatosis, and Hodgkin's disease.

In the adult, carcinomatosis of bone is much the most important cause of this type of anæmia; Vaughan's 8 cases were from a series of 55 carcinomatous patients of whom 24 had bone lesions. The incidence of leuco-erythroblastic anæmia in carcinomatosis did not seem to be influenced by the nature of the primary growth, the length of history, the degree of skeletal involvement, or the character of the bony change (osteolytic or osteoplastic). Nor was any relation found between the degree of anæmia and the incidence of leuco-erythroblastic anæmia. Thus one patient with a red-cell count of 5,300,000 per c.mm. had as many as 106 nucleated red cells per 200 leucocytes, while another patient with a red-cell count down to 3,400,000 per c.mm. had only 1 nucleated red cell per 200 leucocytes (Vaughan 1936).

Pathological examination by Vaughan revealed an increase of red-marrow in patients with carcinomatosis and leuco-erythroblastic anæmia, and she came to the conclusion that the blood picture was probably the result of dyshæmopoiesis due to the foreign tissue in the marrow disturbing the nutrition of the erythropoietic tissue. This anæmia, however, is non-specific, and it may be that the presence of immature cells is due to stimulation of the bone-marrow rather than to actual interference with its nutrition.

CASE-RECORDS

The 6 patients with carcinoma of the prostate and secondary bone metastases, whose histories I shall now describe, were encountered in a general medical outpatient department over a period of three years. It was not possible to verify the diagnosis histologically. The estimations of serum acid and alkaline phosphatase were done by the methods of Gutman and Gutman (1938) and King and Armstrong (1934) respectively.

be roused. The stupor persisted. About three months ago she had badly "ricked" her neck, momentarily thinking it was broken. Subsequently, to prevent or ease pain, she would clasp her hands to the back of her head and neck when coughing; and seldom did she pass a night without sitting up in bed and rubbing her neck with embrocation. Her gait had been rather unsteady for two months. She had never complained of dizziness, headache, or impaired vision. No increase in the size of her head had been remarked, nor was any head injury remembered. A purulent right aural discharge had recurred occasionally since childhood. Increasing deafness had been noted for eighteen months.

Examination.—Patient comatose, but responded to painful stimuli by opening her eyes and moving her limbs, though quite oblivious of her surroundings. General condition good. Temperature 104°, pulse-rate 120. Head abnormally large and typical of Paget's disease; any movement seemed painful. Right mastoid slightly œdematous; pressure greatly resented and evoked much grimacing. Neck very short; no retronuchal rigidity. Both eyes prominent; pupils sluggish to light; optic discs blurred, especially on right side. Deep reflexes active and equal, abdominal reflexes absent, plantar responses equivocal. Incontinence of urine. Eardrums opaque and thickened, upper part of right one inflamed. Blood-pressure 170/110 mm. Hg. Urine contained albumin +, trace of sugar, and acetone + +.

Progress and Treatment.—Next morning a mild erysipeloid eruption was apparent on the upper part of the forehead. No increase of papillœdema. Careful lumbar puncture yielded a clear and colourless fluid under pressure of 200 mm. rising to 250 mm. with right jugular compression; protein content 15 mg. per 100 ml.; one lymphocyte per c.mm. counted. Slight subsequent lessening of the coma. White-cell count 36,000 per c.mm. (polymorphs 34,560, lymphocytes 720, monocytes 720).

A provisional diagnosis of right mastoiditis and associated temporosphenoidal abscess was made, and penicillin (200,000 units intramuscularly every four hours) was started. After consultation, right radical mastoidectomy was performed: bone very spongy, antrum located at a very great depth; middle ear filled with granulations; complete absence of all ossicles except handle of malleus; dura exposed, seen to be slightly bulging and covered with granulations; brain probed and a gush of cerebrospinal fluid obtained, no pus; lateral sinus exposed, healthy; plastic flap cut and wound closed. When she recovered from the anæsthetic, general condition seen to be still good; depth of coma, if anything, lighter. About sixteen hours later, however, she became unconscious and she died soon afterwards.

Post-mortem Examination.—The appearance of the *skull* was typical of advanced Paget's disease. Maximal circumference 64 cm. Anteroposterior diameter 21·7 cm. Transverse diameter 18·0 cm. Vault very soft and vascular; thickness averaged 2·0 cm. Base grossly deformed. Floor of posterior fossa raised; lateral margins of foramen magnum level with the superior borders of petrous temporal bones. Wide pituitary fossa. Recent clean right radical mastoidectomy wound evident. The *other bones* showed no naked-eye evidence of osteitis deformans.

There was moderate flattening of the convolutions of the *brain*. Cerebellar hemispheres much flattened; tonsils herniated into spinal canal on each side of upper cervical cord, the right one more than the left (fig. 1). Anterior grooving of medulla where pressed against rim of foramen magnum. Section revealed an internal communicating hydrocephalus, with moderate dilatation of all four ventricles. No meningeal adhesions or thickening in region of incisura tentorii. The *pituitary gland* was saucer-shaped with concavity upwards; weight 1·3 g.; no histological abnormality.

No significant pathological change was seen in the *heart*; weight 420 g. The *aorta* showed a moderate degree of atheroma. Basal congestion and slight generalised œdema of the *lungs*. Cholesterosis present in the *gall-bladder*, which contained two mixed stones. The *kidneys* were slightly smaller than average; outer surfaces smooth; some relative cortical reduction; stained sections showed early hypertensive changes.

X-ray Examination (posthumous).—The appearance of the skull was that of advanced Paget's disease (fig. 2). Gross thickening, especially in frontal region and vertex, where thickness measured 3·2 cm., the average being 2 cm. Region of foramen magnum invaginated, with upward and forward displacement of atlas and axis. Angle formed by plane of hard palate and that of atlas (Bull 1946) was 17°; normally the planes are roughly parallel. Posterior fossa much narrowed. Sella turcica grossly widened (anteroposterior diameter 2·25 cm.); posterior clinoids distorted and eroded. Radiography of the other bones showed early Paget's changes in the right ilium.

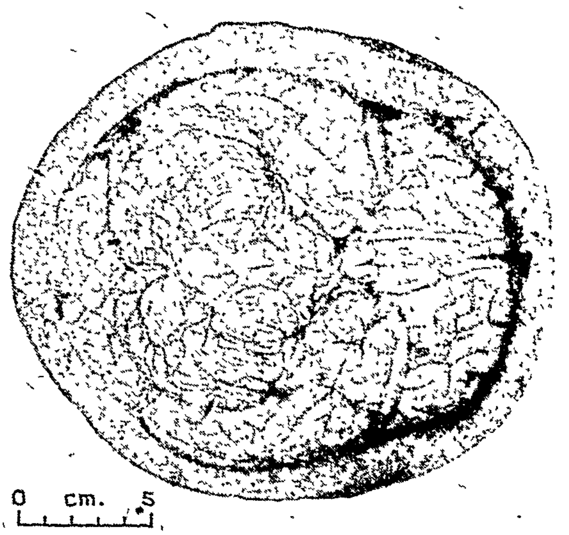

Fig. 1—Thickened vault of skull and base of brain showing flattening of cerebellar hemispheres, herniation of tonsils, and distortion of medulla.

DISCUSSION

Although platybasia was mentioned by Rokitansky as long ago as 1844 (Ebenius 1934), it has had scant attention in the literature, especially in this country. Boogard (1868) gave a detailed account of the changes in the skull, and Homén (1901) correlated neurological and pathological findings. Schüller (1911) made the first radiological diagnosis. Chamberlain (1939) aroused an interest in the subject that would doubtless have been greater but for the intervention of the war. He diagnosed "basilar impression" if the odontoid process projected above a line drawn from the dorsal lip of the foramen magnum to the dorsal margin of the hard palate. Moreton (1943), using this method, collected 139 cases, of which 41 had congenital changes in the cervical portion of the spinal column and 98 showed no such abnormality. He stated that multiple sclerosis had to be excluded in 5 of the latter cases, and that 6 of them had Paget's disease with symptoms only of the primary condition. Saunders (1943), however, showed that 35 out of a 100 normal people examined had odontoid processes projecting above Chamberlain's line. Apart from Moreton's series we have been able to find only 6 published cases of acquired basilar invagination, 5 secondary to Paget's disease—1 reported by Ray (1942), and four by Bull (1946)—and 1 due to osteogenesis imperfecta (Ray 1942). Only Ray's 2 patients showed involvement of the central nervous system.

Our case was wrongly diagnosed as mastoiditis (possibly complicated by cerebral abscess) on the history of chronic intermittent aural discharge and increasing deafness, and the demonstration of apparent mastoid tenderness and œdema, inflamed drum, fever, polymorphonuclear leucocytosis, slight papillœdema, and coma. The subsequent mild erysipeloid infection, improved incidentally by the penicillin exhibited, was considered quite inadequate to account for the symptoms (though evidently it caused the fever and leucocytosis). The possibility of basilar invagination never occurred to us.

Yet ample evidence was there. First, the history of pain in the back of the head and neck, aggravated or induced by coughing, and subsequent unsteadiness of

complain of weakness and general lethargy along with loss of weight. The prostate was diagnosed as malignant on rectal examination in four cases, but the prostate of cases 1 and 2 did not become clinically malignant until six months after the first attendance.

Cases 1, 2, and 4 showed initial serum acid phosphatase values above 10 units, but cases 3 and 5 showed only moderate elevation (5·5 and 7 units) and case 6 no rise at all. It is important to note however that cases 3 and 5 showed a significant fall in titre with alcohol treatment, and case 6 also showed a decrease but to a lesser degree. It has been pointed out above that similar slight elevations of serum acid phosphatase may occur occasionally in other conditions, especially in Paget's disease. I have examined the sera of 6 patients with Paget's disease and found the acid phosphatase normal in all except one, in whom the value was 13 units on repeated estimation. Alcohol treatment of the sera in these cases caused no lowering of the acid phosphatase even in the patient with 13 units.

Anæmia, which may be rapidly progressive (case 1), was found in all 6 patients. The initial hæmoglobin varied between 7·7 and 11·0 g. per 100 ml. and the colour-index was about 0·9 in each case. The white-cell count varied between 3700 and 11,300 per c.mm., and myelocytes were found in 3 patients while normoblasts were present in 4. In the only blood-count on case 3 no immature cells were found. This type of anæmia may be a very early feature (cases 1 and 2), so that when it is found, all possible primary sites of secondary bone metastases should be investigated. The spleen was definitely enlarged in case 5, possibly owing to myeloid metaplasia. Vaughan (1936) also noted such an enlargement in one patient with leuco-erythroblastic anæmia due to carcinoma.

From the case-histories it can be seen that interpretation of X-ray films of the pelvis can be extremely difficult; it may be almost impossible to decide whether an osteoplastic lesion is due to Paget's disease or to prostatic metastases in bone. Increase in the thickness of the bone is said to favour the former (Shanks et al. 1939). Paget's disease was actually mentioned in 4 of the cases (1, 2, 3, and 4), but after further consideration the changes found in cases 1 and 2 were said to be more suggestive of carcinoma. Case 4 was reported to have secondary bone metastases in addition to Paget's disease, but case 3 showed changes which were interpreted as solely due to Paget's disease. It may be, of course, that cases 3 and 4 have both diseases; but this is extremely difficult to prove in the absence of histological examination. Cases 1 and 6 illustrate the well-known fact that clinical symptoms of metastases may appear many months before radiological changes become apparent.

Clinically, the patients were enormously improved by treatment. In each case the bone pains were relieved in less than a week. This effect is most dramatic and can be used as a therapeutic test. Nocturia and dysuria, when present, were only slightly improved, in spite of the fact that the prostate usually decreased in size. The appetite and weight returned to normal. With stilbœstrol the serum acid phosphatase fell in each case, but normal figures were only obtained in 2 out of 5 patients (cases 3 and 5), though the amount in case 1 came down almost to normal. The method of alcohol inactivation caused almost complete disappearance of prostatic phosphatase in case 5 only. The total serum acid phosphatase of case 6 was, of course, normal even before treatment; but there was a significant amount of prostatic phosphatase, which decreased with treatment. The serum alkaline phosphatase slowly rose and later fell in cases 1 and 3 and this has been interpreted as evidence of osteoblastic activity associated with healing (Huggins and Hodges 1941). When cases 2 and 3 relapsed there was no rise in either the acid or alkaline phosphatase, but when case 1 relapsed, as he did on two occasions, there was a decided rise in the serum acid phosphatase.

A study was also made of the effect of stilbœstrol on the serum acid and alkaline phosphatase of 6 patients with Paget's disease. The acid phosphatase was not affected, and the alkaline phosphatase either remained stationary or slowly fell. Thus examination of the effect of œstrogens on the serum acid and alkaline phosphatase may help in deciding between Paget's disease and secondary prostatic metastases; moreover, as already noted, the rapid disappearance of pain in the latter and not the former will soon decide the issue.

The anæmia was not affected by iron or liver preparations. Stilbœstrol also had no effect on the hæmoglobin but the immature cells disappeared in case 1 after the start of this treatment. Stilbœstrol however had no effect on the number of immature cells in case 5.

Œstrogen therapy of carcinoma of the prostate is not a cure; it is merely palliative (Herger and Sauer 1941). Relapses do eventually occur and usually the patient is then resistant to further treatment, as is shown in cases 2 and 3.

SUMMARY

1. The serum acid and alkaline phosphatase levels were estimated in 6 patients suffering from prostatic carcinoma with metastases in bone.

2. The inactivation of prostatic phosphatase by alcohol has been shown to be of diagnostic value, especially in those cases where the total serum acid phosphatase is only slightly raised.

3. A leuco-erythroblastic type of anæmia has been noted in 4 patients.

4. The effects of stilbœstrol on the clinical course, on the serum acid and alkaline phosphatase, and on the anæmia have been observed.

5. Attention has again been directed to the similarity in the radiological appearances of the pelvis of Paget's disease and osteoplastic metastases. Differences in the behaviour of the acid phosphatase in these two conditions have been described.

I wish to thank Dr. A. H. Holmes, Dr. C. S. D. Don, and Dr. N. Kletts for permission to study their patients and for their encouragement and advice. Mr. H. Varley, M.SC., of the department of clinical pathology of the Manchester Royal Infirmary, kindly performed the phosphatase estimations. My thanks are also due to Dr. E. D. Gray and Dr. R. G. Reid for help in the interpretation of the X-ray films. For the photographs I am indebted to Mr. J. Kilshaw of the department of medical photography of the infirmary.

"... it is clear that a new method should be introduced, by which housing subsidies are distributed only to municipal tenants who need them. The subsidies would be withdrawn from the houses to which they are at present attached and the rents fixed to cover costs. These rents would then be charged to tenants who could afford them.... Parallel to this revision of rents ... special arrangements would be made to help those families in need, by granting them a rebate on the rent."—*Planning*, April 24, p. 271. Published by P.E.P., 16, Queen Anne's Gate, London, S.W.1.

Case 1.—Aged 73; admitted February, 1946, with a history of weakness for three months, diffuse aching pains and irregular pyrexia for some weeks, loss of 1 st. in weight, and nocturia, not worse recently. On admission his temperature was 100°F, the patient appeared anæmic and there was a moderate firm enlargement of the prostate. Blood-count: red cells 3,960,000 per c.mm.; Hb 9·9 g. per 100 ml.; colour-index (C.I.) 0·91; white cells 11,300 per c.mm. (Differential count normal apart from 3·5% myelocytes.) Serum acid phosphatase 12 units (alcohol-stable fraction 2 units), alkaline phosphatase 33 units. Radiography of chest normal; pelvis and lumbar spine showed generalised osteoporosis with increased trabeculation, suggesting fibrous type of Paget's disease (fig. 1). Bone-marrow: hypoplasia without evidence of leukæmic change. Thus blood-examination showed leuco-erythroblastic anæmia on admission; but it was not until seven months later that radiography definitely confirmed the presence of metastases in the pelvis and lumbar spine (fig. 2). Stilbœstrol caused a fall in serum acid phosphatase (but a normal value was never obtained), a gradual rise (followed later by a fall) in serum alkaline phosphatase, and disappearance of immature cells from the peripheral blood. Neither iron, liver, nor stilbœstrol affected the hæmoglobin value. The patient relapsed in August, 1946, and then responded to increased dosage of stilbœstrol; but in September, 1947, when he relapsed again (fig. 3), presumably because he omitted to take the tablets, he failed to respond to stilbœstrol, dienœstrol, or orchidectomy. He lived for twenty-two months after the diagnosis was made.

The mode of presentation with irregular pyrexia and generalised pains is noteworthy. There had been no recent disturbance of micturition, and on rectal examination the surgeons considered the prostatic enlargement to be benign. Only six months later did it become definitely hard and clinically malignant.

Case 2.—Aged 62; admitted in February, 1947, with symptoms suggesting subacute intestinal obstruction. Pallor; slight enlargement of prostate. X-ray examination of colon negative; symptoms disappeared after enemata. Blood-count: red cells 3,450,000 per c.mm.; Hb 8·6 g. per 100 ml.; C.I. 0·90; white cells 4600 per c.mm. (Differential count normal apart from 2% myelocytes and 1 normoblast per 200 leucocytes.)

Readmitted in August, 1947, with four months' history of severe lumbar backache and pain in both thighs. Prostate enlarged and fairly hard. Blood-count: red cells 4,010,000 per c.mm.; Hb 10·8 g.; C.I. 0·97; white cells 4000 per c.mm. (Differential count normal and no immature cells.) Serum acid phosphatase 37 units (alcohol-stable fraction 6·3 units), alkaline phosphatase 69 units.

X-ray appearances of the pelvis suggested Paget's disease, though phosphatase values indicated secondary bony lesions from a carcinomatous prostate. The clinical response to œstrogen therapy was good, but when the patient relapsed increased dosage had no effect. He lived for thirteen months after the diagnosis was made.

The early leuco-erythroblastic anæmia should be noted; also, throughout the illness, the paucity of symptoms suggestive of prostatic disease.

Case 3.—Aged 68. In August, 1948, complained of lumbar backache and pain down front of both thighs (five weeks). Prostate enlarged, hard, and nodular. Nocturia had been present for two years but there was no recent exacerbation, and the predominant symptom was bone pain. Clinically there was no doubt that the prostate was malignant, but X-ray examination of the pelvis and lumbar spine suggested Paget's disease; no other bones affected. The initial acid phosphatase value was only 5·5 units, but of this 3·1 units were alcohol-labile. There was a good initial response to œstrogen therapy with a fall in the alcohol-labile fraction of acid phosphatase and a rise and subsequent fall in alkaline phosphatase. After seven months there was a relapse with no further response to œstrogens. The patient lived for eleven months after the diagnosis was made.

Case 4.—Aged 74. In August, 1948, he had lumbar backache and pain radiating down the front of right thigh (six weeks). In May, 1949, when I first saw him, the pain had gone into the left thigh. During the last six months there had been nocturia, and more recently dysuria with poor stream and terminal dribbling. Anæmic, with tenderness over the lumbosacral spine; prostate enlarged and hard. Blood-count: red cells 3,440,000 per c.mm.; Hb 10·1 g.; C.I. 0·99; white cells 6800 per c.mm. (Differential count normal apart from 8 normoblasts per 200 leucocytes.) Serum acid phosphatase 510 units (alcohol-stable fraction 9 units), alkaline phosphatase 91 units. This serum acid phosphatase value was the highest obtained in the series, and though œstrogen therapy failed to bring it down to normal, it caused the bone pain to disappear. Œdema was produced by the large dosage employed but subsided when the amount of œstrogen was reduced. Normoblasts were found in the first blood-count but not subsequently. The X-ray films suggested Paget's disease, this time in addition to secondary bone metastases. This patient is still under observation.

Again the first major symptom was pain in the lumbar region and thighs.

Case 5.—Aged 73. In June, 1949, complained of four months' flatulence, which had recently improved, sacral ache, and pain in both thighs together with a loss of 1 st in weight. Nocturia for several years, recently worse; now dysuria with poor stream and terminal dribbling.

He was a pale man in much pain, with hard mobile glands in both supraclavicular fossæ and left posterior triangle. Tenderness over sacral spine and outer aspect of right femur; spleen easily palpable; prostate enlarged, irregular, and hard. Blood-count: red cells 3,070,000 per c.mm.; Hb 8·3 g.; C.I. 0·92; white cells 3700 per c.mm. (Differential count normal apart from 4 normoblasts per 200 leucocytes and 7% myelocytes.) Radiography of pelvis and lumbar spine showed osteoplastic secondaries. Biopsy of a gland revealed a highly anaplastic carcinoma containing necrotic material. As in case 3, the serum acid phosphatase value was only slightly above normal but again a significant amount (3 units) was alcohol-labile. Stilbœstrol brought about a good clinical response and the acid phosphatase titre fell to normal, but there was no effect on the anæmia or the leuco-erythroblastic picture. The patient is still under observation. This was the only case in which the spleen was palpable.

Case 6.—Aged 61. In August, 1949, admitted with pain in the lower cervical spine extending down the right arm (seven months). More recently this had spread down left arm, and coughing produced paræsthesiæ in both arms. No disturbance of micturition. A mass of hard immobile glands in right supraclavicular fossa; prostate enlarged, hard, and nodular. Blood-count: red cells 3,950,000 per c.mm.; Hb 10·7 g.; C.I. 0·90; white cells 6500 per c.mm. (Differential count normal.) X-ray films of the cervical spine suggested some erosion of spinous process of the 6th cervical vertebra. After five days' treatment with stilbœstrol, 15 mg. daily, pains and paræsthesiæ much improved. The mass of glands disappeared after four weeks. Initial total serum acid phosphatase was within the normal range but inactivation by alochol showed the presence on one occasion of 1·3 units of prostatic phosphatase, and on another of 0·9 unit. These figures were not conclusive but taken in conjunction with the clinical picture indicate that the diagnosis was correct. Though the alcohol-labile fraction of serum acid phosphatase was only slightly raised before treatment, it nevertheless decreased with œstrogen administration. The patient is still under observation.

There was no disturbance of micturition and the predominant complaint was pain in the neck and down both arms. In fact the patient had been treated for a short time in the outpatient department by means of physiotherapy. The dramatic response to stilbœstrol acted as a therapeutic test.

DISCUSSION

All these patients gave a history of aching pain in the spine, usually in the lumbar region, with radiation into the limbs. When the legs were affected, as was usually the case, the pain was not of sciatic distribution and was usually bilateral, constant, and severe. The symptoms arising as a result of prostatic enlargement may be entirely absent (case 6) and when present are often of several years' duration; in 2 cases only (4 and 5) was there a recent exacerbation. The patients often

complain of weakness and general lethargy along with loss of weight. The prostate was diagnosed as malignant on rectal examination in four cases, but the prostate of cases 1 and 2 did not become clinically malignant until six months after the first attendance.

Cases 1, 2, and 4 showed initial serum acid phosphatase values above 10 units, but cases 3 and 5 showed only moderate elevation (5·5 and 7 units) and case 6 no rise at all. It is important to note however that cases 3 and 5 showed a significant fall in titre with alcohol treatment, and case 6 also showed a decrease but to a lesser degree. It has been pointed out above that similar slight elevations of serum acid phosphatase may occur occasionally in other conditions, especially in Paget's disease. I have examined the sera of 6 patients with Paget's disease and found the acid phosphatase normal in all except one, in whom the value was 13 units on repeated estimation. Alcohol treatment of the sera in these cases caused no lowering of the acid phosphatase even in the patient with 13 units.

Anæmia, which may be rapidly progressive (case 1), was found in all 6 patients. The initial hæmoglobin varied between 7·7 and 11·0 g. per 100 ml. and the colour-index was about 0·9 in each case. The white-cell count varied between 3700 and 11,300 per c.mm., and myelocytes were found in 3 patients while normoblasts were present in 4. In the only blood-count on case 3 no immature cells were found. This type of anæmia may be a very early feature (cases 1 and 2), so that when it is found, all possible primary sites of secondary bone metastases should be investigated. The spleen was definitely enlarged in case 5, possibly owing to myeloid metaplasia. Vaughan (1936) also noted such an enlargement in one patient with leuco-erythroblastic anæmia due to carcinoma.

From the case-histories it can be seen that interpretation of X-ray films of the pelvis can be extremely difficult; it may be almost impossible to decide whether an osteoplastic lesion is due to Paget's disease or to prostatic metastases in bone. Increase in the thickness of the bone is said to favour the former (Shanks et al. 1939). Paget's disease was actually mentioned in 4 of the cases (1, 2, 3, and 4), but after further consideration the changes found in cases 1 and 2 were said to be more suggestive of carcinoma. Case 4 was reported to have secondary bone metastases in addition to Paget's disease, but case 3 showed changes which were interpreted as solely due to Paget's disease. It may be, of course, that cases 3 and 4 have both diseases; but this is extremely difficult to prove in the absence of histological examination. Cases 1 and 6 illustrate the well-known fact that clinical symptoms of metastases may appear many months before radiological changes become apparent.

Clinically, the patients were enormously improved by treatment. In each case the bone pains were relieved in less than a week. This effect is most dramatic and can be used as a therapeutic test. Nocturia and dysuria, when present, were only slightly improved, in spite of the fact that the prostate usually decreased in size. The appetite and weight returned to normal. With stilbœstrol the serum acid phosphatase fell in each case, but normal figures were only obtained in 2 out of 5 patients (cases 3 and 5), though the amount in case 1 came down almost to normal. The method of alcohol inactivation caused almost complete disappearance of prostatic phosphatase in case 5 only. The total serum acid phosphatase of case 6 was, of course, normal even before treatment; but there was a significant amount of prostatic phosphatase, which decreased with treatment. The serum alkaline phosphatase slowly rose and later fell in cases 1 and 3 and this has been interpreted as evidence of osteoblastic activity associated with healing (Huggins and Hodges 1941). When cases 2 and 3 relapsed there was no rise in either the acid or alkaline phosphatase, but when case 1 relapsed, as he did on two occasions, there was a decided rise in the serum acid phosphatase.

A study was also made of the effect of stilbœstrol on the serum acid and alkaline phosphatase of 6 patients with Paget's disease. The acid phosphatase was not affected, and the alkaline phosphatase either remained stationary or slowly fell. Thus examination of the effect of œstrogens on the serum acid and alkaline phosphatase may help in deciding between Paget's disease and secondary prostatic metastases; moreover, as already noted, the rapid disappearance of pain in the latter and not the former will soon decide the issue.

The anæmia was not affected by iron or liver preparations. Stilbœstrol also had no effect on the hæmoglobin but the immature cells disappeared in case 1 after the start of this treatment. Stilbœstrol however had no effect on the number of immature cells in case 5.

Œstrogen therapy of carcinoma of the prostate is not a cure; it is merely palliative (Herger and Sauer 1941). Relapses do eventually occur and usually the patient is then resistant to further treatment, as is shown in cases 2 and 3.

SUMMARY

1. The serum acid and alkaline phosphatase levels were estimated in 6 patients suffering from prostatic carcinoma with metastases in bone.

2. The inactivation of prostatic phosphatase by alcohol has been shown to be of diagnostic value, especially in those cases where the total serum acid phosphatase is only slightly raised.

3. A leuco-erythroblastic type of anæmia has been noted in 4 patients.

4. The effects of stilbœstrol on the clinical course, on the serum acid and alkaline phosphatase, and on the anæmia have been observed.

5. Attention has again been directed to the similarity in the radiological appearances of the pelvis of Paget's disease and osteoplastic metastases. Differences in the behaviour of the acid phosphatase in these two conditions have been described.

I wish to thank Dr. A. H. Holmes, Dr. C. S. D. Don, and Dr. N. Kletts for permission to study their patients and for their encouragement and advice. Mr. H. Varley, M.SC., of the department of clinical pathology of the Manchester Royal Infirmary, kindly performed the phosphatase estimations. My thanks are also due to Dr. E. D. Gray and Dr. R. G. Reid for help in the interpretation of the X-ray films. For the photographs I am indebted to Mr. J. Kilshaw of the department of medical photography of the infirmary.

"... it is clear that a new method should be introduced, by which housing subsidies are distributed only to municipal tenants who need them. The subsidies would be withdrawn from the houses to which they are at present attached and the rents fixed to cover costs. These rents would then be charged to tenants who could afford them.... Parallel to this revision of rents ... special arrangements would be made to help those families in need, by granting them a rebate on the rent."—*Planning*, April 24, p. 271. Published by P.E.P., 16, Queen Anne's Gate, London, S.W.1.

Case 1.—Aged 73; admitted February, 1946, with a history of weakness for three months, diffuse aching pains and irregular pyrexia for some weeks, loss of 1 st. in weight, and nocturia, not worse recently. On admission his temperature was 100°F, the patient appeared anæmic and there was a moderate firm enlargement of the prostate. Blood-count: red cells 3,960,000 per c.mm.; Hb 9·9 g. per 100 ml.; colour-index (C.I.) 0·91; white cells 11,300 per c.mm. (Differential count normal apart from 3·5% myelocytes.) *Serum acid phosphatase* 12 units (alcohol-stable fraction 2 units), alkaline phosphatase 33 units. Radiography of chest normal; pelvis and lumbar spine showed generalised osteoporosis with increased trabeculation, suggesting fibrous type of Paget's disease (fig. 1). Bone-marrow: hypoplasia without evidence of leukæmic change. Thus blood-examination showed leuco-erythroblastic anæmia on admission; but it was not until seven months later that radiography definitely confirmed the presence of metastases in the pelvis and lumbar spine (fig. 2). Stilbœstrol caused a fall in serum acid phosphatase (but a normal value was never obtained), a gradual rise (followed later by a fall) in serum alkaline phosphatase, and disappearance of immature cells from the peripheral blood. Neither iron, liver, nor stilbœstrol affected the hæmoglobin value. The patient relapsed in August, 1946, and then responded to increased dosage of stilbœstrol; but in September, 1947, when he relapsed again (fig. 3), presumably because he omitted to take the tablets, he failed to respond to stilbœstrol, dienœstrol, or orchidectomy. He lived for twenty-two months after the diagnosis was made.

The mode of presentation with irregular pyrexia and generalised pains is noteworthy. There had been no recent disturbance of micturition, and on rectal examination the surgeons considered the prostatic enlargement to be benign. Only six months later did it become definitely hard and clinically malignant.

Case 2.—Aged 62; admitted in February, 1947, with *symptoms suggesting subacute intestinal obstruction. Pallor*; slight enlargement of prostate. X-ray examination of colon negative; symptoms disappeared after enemata. Blood-count: red cells 3,450,000 per c.mm.; Hb 8·6 g. per 100 ml.; C.I. 0·90; white cells 4600 per c.mm. (Differential count normal apart from 2% myelocytes and 1 normoblast per 200 leucocytes.)

Readmitted in August, 1947, with four months' history of severe lumbar backache and pain in both thighs. Prostate enlarged and fairly hard. Blood-count: red cells 4,010,000 per c.mm.; Hb 10·8 g.; C.I. 0·97; white cells 4000 per c.mm. (Differential count normal and no immature cells.) Serum acid phosphatase 37 units (alcohol-stable fraction 6·3 units), alkaline phosphatase 69 units.

X-ray appearances of the pelvis suggested Paget's disease, though phosphatase values indicated secondary bony lesions from a carcinomatous prostate. The clinical response to œstrogen therapy was good, but when the patient relapsed increased dosage had no effect. He lived for thirteen months after the diagnosis was made.

The early leuco-erythroblastic anæmia should be noted; also, throughout the illness, the paucity of symptoms suggestive of prostatic disease.

Case 3.—Aged 68. In August, 1948, complained of lumbar backache and pain down front of both thighs (five weeks). Prostate enlarged, hard, and nodular. Nocturia had been present for two years but there was no recent exacerbation, and the predominant symptom was bone pain. Clinically there was no doubt *that the prostate was malignant*, but X-ray examination of the pelvis and lumbar spine suggested Paget's disease; no other bones affected. The *initial* acid phosphatase value was only 5·5 units, but of this 3·1 units were alcohol-labile. There was a good initial response to œstrogen therapy with a fall in the alcohol-labile fraction of acid phosphatase and a rise and subsequent fall in alkaline phosphatase. After seven months there was a relapse with no further response to œstrogens. The patient lived for eleven months after the diagnosis was made.

Case 4.—Aged 74. In August, 1948, he had lumbar backache and pain radiating down the front of right thigh (six weeks). In May, 1949, when I first saw him, the pain had gone into the left thigh. During the last six months there had been nocturia, and more recently dysuria with poor stream and terminal dribbling. Anæmic, with tenderness over the lumbosacral spine; prostate enlarged and hard. Blood-count: red cells 3,440,000 per c.mm.; Hb 10·1 g.; C.I. 0·99; white cells 6800 per c.mm. *(Differential count* normal apart from 8 normoblasts per 200 leucocytes.) Serum acid phosphatase 510 units (alcohol-stable fraction 9 units), alkaline phosphatase 91 units. This serum acid phosphatase value was the highest obtained in the series, and *though œstrogen therapy failed to bring it down to normal, it caused the bone pain to disappear.* Œdema was produced by the large dosage employed but subsided when the amount of œstrogen was reduced. *Normoblasts were found in the* first blood-count but not subsequently. The X-ray films suggested Paget's disease, this time in addition to secondary bone metastases. This patient is still under observation.

Again the first major symptom was pain in the lumbar region and thighs.

Case 5.—Aged 73. In June, 1949, complained of four months' flatulence, which had recently improved, sacral ache, and pain in both thighs together with a loss of 1 st in weight. Nocturia for several years, recently worse; now dysuria with poor stream and terminal dribbling.

He was a pale man in much pain, with hard mobile glands in both supraclavicular fossæ and left posterior triangle. Tenderness over sacral spine and outer aspect of right femur; spleen easily palpable; prostate enlarged, irregular, and hard. Blood-count: red cells 3,070,000 per c.mm.; Hb 8·3 g.; C.I. 0·92; white cells 3700 per c.mm. (Differential count normal apart from 4 normoblasts per 200 leucocytes and 7% myelocytes.) Radiography of pelvis and lumbar spine showed osteoplastic secondaries. Biopsy of a gland revealed a highly anaplastic carcinoma containing necrotic material. As in case 3, the serum acid phosphatase value was only slightly above normal but again a significant amount (3 units) was alcohol-labile. Stilbœstrol brought about a good clinical response and the acid phosphatase titre fell to normal, but there was no effect on the anæmia or the leuco-erythroblastic picture. The patient is still under observation. This was the only case in which the spleen was palpable.

Case 6.—Aged 61. In August, 1949, admitted with pain in the lower cervical spine extending down the right arm (seven months). More recently this had spread down left arm, and coughing produced paræsthesiæ in both arms. No disturbance of micturition. A mass of hard immobile glands in right supraclavicular fossa; prostate enlarged, hard, and nodular. Blood-count: red cells 3,950,000 per c.mm.; Hb 10·7 g.; C.I. 0·90; white cells 6500 per c.mm. (Differential count normal.) X-ray films of the cervical spine suggested some erosion of spinous process of the 6th cervical vertebra. *After five* days' treatment with stilbœstrol, 15 mg. daily, pains and paræsthesiæ much improved. The mass of glands disappeared after four weeks. Initial total serum acid phosphatase was within the normal range but inactivation by alochol showed the presence on one occasion of 1·3 *units of prostatic phosphatase*, and on another of 0·9 unit. These figures were not conclusive but taken in conjunction with the clinical picture indicate that the diagnosis was correct. Though the alcohol-labile fraction of serum acid phosphatase was only slightly raised before treatment, it nevertheless decreased with œstrogen administration. The patient is still under observation

There was no disturbance of micturition and the predominant complaint was pain in the neck and down both arms. In fact the patient had been treated for a short time in the outpatient department by means of physiotherapy. The dramatic response to stilbœstrol acted as a therapeutic test.

DISCUSSION

All these patients gave a history of aching pain in the spine, usually in the lumbar region, with radiation into the limbs. When the legs were affected, as was usually the case, the pain was not of sciatic distribution and was usually bilateral, constant, and severe. The symptoms arising as a result of prostatic enlargement may be entirely absent (case 6) and when present are often of several years' duration; in 2 cases only (4 and 5) was there a recent exacerbation. The patients often

complain of weakness and general lethargy along with loss of weight. The prostate was diagnosed as malignant on rectal examination in four cases, but the prostate of cases 1 and 2 did not become clinically malignant until six months after the first attendance.

Cases 1, 2, and 4 showed initial serum acid phosphatase values above 10 units, but cases 3 and 5 showed only moderate elevation (5·5 and 7 units) and case 6 no rise at all. It is important to note however that cases 3 and 5 showed a significant fall in titre with alcohol treatment, and case 6 also showed a decrease but to a lesser degree. It has been pointed out above that similar slight elevations of serum acid phosphatase may occur occasionally in other conditions, especially in Paget's disease. I have examined the sera of 6 patients with Paget's disease and found the acid phosphatase normal in all except one, in whom the value was 13 units on repeated estimation. Alcohol treatment of the sera in these cases caused no lowering of the acid phosphatase even in the patient with 13 units.

Anæmia, which may be rapidly progressive (case 1), was found in all 6 patients. The initial hæmoglobin varied between 7·7 and 11·0 g. per 100 ml. and the colour-index was about 0·9 in each case. The white-cell count varied between 3700 and 11,300 per c.mm., and myelocytes were found in 3 patients while normoblasts were present in 4. In the only blood-count on case 3 no immature cells were found. This type of anæmia may be a very early feature (cases 1 and 2), so that when it is found, all possible primary sites of secondary bone metastases should be investigated. The spleen was definitely enlarged in case 5, possibly owing to myeloid metaplasia. Vaughan (1936) also noted such an enlargement in one patient with leuco-erythroblastic anæmia due to carcinoma.

From the case-histories it can be seen that interpretation of X-ray films of the pelvis can be extremely difficult; it may be almost impossible to decide whether an osteoplastic lesion is due to Paget's disease or to prostatic metastases in bone. Increase in the thickness of the bone is said to favour the former (Shanks et al. 1939). Paget's disease was actually mentioned in 4 of the cases (1, 2, 3, and 4), but after further consideration the changes found in cases 1 and 2 were said to be more suggestive of carcinoma. Case 4 was reported to have secondary bone metastases in addition to Paget's disease, but case 3 showed changes which were interpreted as solely due to Paget's disease. It may be, of course, that cases 3 and 4 have both diseases; but this is extremely difficult to prove in the absence of histological examination. Cases 1 and 6 illustrate the well-known fact that clinical symptoms of metastases may appear many months before radiological changes become apparent.

Clinically, the patients were enormously improved by treatment. In each case the bone pains were relieved in less than a week. This effect is most dramatic and can be used as a therapeutic test. Nocturia and dysuria, when present, were only slightly improved, in spite of the fact that the prostate usually decreased in size. The appetite and weight returned to normal. With stilbœstrol the serum acid phosphatase fell in each case, but normal figures were only obtained in 2 out of 5 patients (cases 3 and 5), though the amount in case 1 came down almost to normal. The method of alcohol inactivation caused almost complete disappearance of prostatic phosphatase in case 5 only. The total serum acid phosphatase of case 6 was, of course, normal even before treatment; but there was a significant amount of prostatic phosphatase, which decreased with treatment. The serum alkaline phosphatase slowly rose and later fell in cases 1 and 3 and this has been interpreted as evidence of osteoblastic activity associated with healing (Huggins and Hodges 1941). When cases 2 and 3 relapsed there was no rise in either the acid or alkaline phosphatase, but when case 1 relapsed, as he did on two occasions, there was a decided rise in the serum acid phosphatase.

A study was also made of the effect of stilbœstrol on the serum acid and alkaline phosphatase of 6 patients with Paget's disease. The acid phosphatase was not affected, and the alkaline phosphatase either remained stationary or slowly fell. Thus examination of the effect of œstrogens on the serum acid and alkaline phosphatase may help in deciding between Paget's disease and secondary prostatic metastases: moreover, as already noted, the rapid disappearance of pain in the latter and not the former will soon decide the issue.

The anæmia was not affected by iron or liver preparations. Stilbœstrol also had no effect on the hæmoglobin but the immature cells disappeared in case 1 after the start of this treatment. Stilbœstrol however had no effect on the number of immature cells in case 5.

Œstrogen therapy of carcinoma of the prostate is not a cure; it is merely palliative (Herger and Sauer 1941). Relapses do eventually occur and usually the patient is then resistant to further treatment, as is shown in cases 2 and 3.

Medical Societies

ROYAL SOCIETY OF MEDICINE

Chronic Œdema of the Leg

THE section of surgery met on April 5, with MR. DIGBY CHAMBERLAIN, the president, in the chair, to discuss the treatment of chronic œdema of the leg.

Prof. A. M. BOYD said that from analysis of 673 cases a tentative classification had been adopted: (1) venous, (2) erythrocyanoid, (3) lymphœdematous, and (4) angiomatoid. Mixtures of several types were frequently seen. Venous œdema might be complicated by lymphœdema due to spread of inflammation through the vein walls to the perivenous lymphatic vessels; or erythrocyanosis frigida might be followed later by a "white leg," which in its turn might be complicated by inflammatory œdema. The angiomatoid group were usually seen in the pure state.

Describing the routine investigation of cases at Manchester, Professor Boyd said that patients were photographed, their limb-size was measured, and angiograph and soft-tissue radiographs were taken. Venous pressures were measured by a modification of the method used by Mr. A. J. Walker, of St. Bartholomew's Hospital. There were two basic types of limb: (1) normal arterial circulation (arteries and veins of normal calibre), and (2) erythrocyanoid type (both arteries and veins small—a half or a third of the normal calibre).

The clinical manifestations of the various œdemas depended on the type of limb involved: for example, a "white leg" would show less tendency to resolve if the limb already had a poor blood-supply. The same applied to lymphœdema.

Iliofemoral thrombosis—the typical "white leg"—other than puerperal in origin, was commonly seen over 40 years of age. Apparently spontaneous iliofemoral thrombosis over the age of 60 years was indicative of malignant disease. Deep phlebitis in the calf veins was usually traumatic in origin. Fungus infection was a frequent cause of otherwise unexplained phlebitis.

Certain cases of "lymphœdema of indefinite origin" were probably venous in origin, due to progressive loss of valves in the deep veins. The contribution of the arterial, venous, and lymphatic factors must be assessed in the individual. Treatment of these œdemas consisted in ascertaining and remedying these factors.

Prof. IAN AIRD emphasised the importance, in the treatment of chronic œdema, of appreciating individual differences. He suggested that solid non-pitting œdema was the result of an original pitting œdema, but that not every case of chronic œdema developed into the non-pitting kind. Why some should proceed to the non-pitting state was not understood, but it was known that for solid œdema a high concentration of protein in the œdema fluid was necessary, and this concentration was likely to be highest when there was complete lymphatic obstruction. In the early stages of pitting œdema, conservative measures were probably sufficient. But consideration should be given at an early stage to the cause of the œdema, because some causes lent themselves to additional specific therapy.

Reviewing the types of cases, Professor Aird pointed out that congenital œdema was becoming less frequent, which raised the question whether the diagnosis had been correct. In some cases chronic œdema was associated with congenital auriculo-ventricular fistula. Œdema associated with bone injury usually improved within a year. A succession of attacks of cellulitis might proceed to chronic, non-pitting lymphœdema, which was not due to obstruction of the lymph pathways so much as to the presence of fixed local antibodies in the tissues; in these cases special treatment in the form of chemotherapy and massage had some success. Quincke's disease could also be treated by massage in the acute stage, and by sympathectomy; but recovery often took place spontaneously after a year. Lymphœdema præcox was the most progressive and intractable of all.

Professor Aird said in summary that the best hope of controlling œdema of the leg was still the elastic bandage initially and the elastic stocking later; the stocking should extend to the groin and be supported by a suspender-belt. Solid œdema could be relieved only operatively, by excision in two stages of the subcutaneous layer and the deep fascia. Amputation was much less often necessary for elephantiasis of the leg than of the arm.

Sir ARCHIBALD McINDOE said that chronic œdema had always been, for the patient, one of the most distressing and disabling conditions, and for the surgeon one of the most disappointing. In tropical climates œdema of the leg might be parasitic in origin; or it might be non-parasitic, due to lymphatic obstruction or other causes.

Listing the types of œdema, Sir Archibald doubted whether Milroy's disease ever occurred outside the famous family which Milroy described. Idiopathic lymphœdema præcox, in adolescent females, was a non-inflammatory condition, probably due to a low-grade inflammatory process. Inflammatory lymphœdema began as an inflammatory attack and spread from the nodal points in the leg, the cause being a streptococcus or a staphylococcus. Secondary lymphœdemas formed a mixed group, covering all other types of œdema. Sir Archibald explained that from his point of view cases of idiopathic lymphœdema præcox and of inflammatory œdema constituted the largest group. With regard to lymphœdema, he felt that undue attention was being given to the venous as opposed to the lymphatic aspect.

Surgical intervention might take the form of reversing the lymph-flow. This had very seldom caused lasting benefit; patients treated in this way needed very careful postoperative elastic bandaging, which they could have had without the operation. The centric obstruction might be traversed by providing a lymphatic bridge—from the leg to the axilla, for instance. This could provide benefit, but it was a difficult and dangerous operation which should only be done by a plastic surgeon.

Sir Archibald described a series of cases in which the lymph-bearing area was removed. The subcutaneous tissue and deep fascia was removed down to the muscle, leaving large skin-flaps no deeper than a Wolfe graft. These dermo-epidermal flaps were then applied. The whole process was carried out at one or more operations. The results were most hopeful, although the operation was only suitable in certain cases. The grafts might act as a strong elastic bandage, or it might be that the removal of the lymphatic tissue was itself curative. The œdema was still left at places where excision could not be done—the toes and the tendo achillis.

Lastly, œdema of the leg was a condition which, in the early stages, should be medically curable, and he looked forward to the time when the inflammatory processes could be brought under control.

Sir HAROLD GILLIES said that the operation of putting a wick across a lymphatic block was the right one where there was a mechanical block, as in lymphœdema præcox and traumatic cases.

Mr. A. J. WALKER described the method of taking venous pressures referred to by Professor Boyd. In this an apparatus was adapted from a sphygmomanometer, with a bottle of fluid and a length of 'Polythene' tube, which was filled with the fluid and inserted into a vein in the foot. The pressure was varied and the point at which blood was seen to flow out into the tube was taken as the reading of the venous pressure. An advantage of this apparatus was that readings could be taken during exercise. As to treatment, Mr. Walker described a series of 25 cases in which venous ligation was performed. Of 21 patients who had been followed up for periods of three to twenty-one months, only 2 were completely relieved of the œdema; in 5 this was absent so long as they wore elastic bandages; in others the improvement was less well-marked, and of all the symptoms the œdema was the one which improved least.

Mr. A. H. RATCLIFFE, D.PHIL., said that analyses had been made of serum and tissue fluids, but from the research point of view the results were "depressingly normal." The fluid in the limb might be described as afferent vascular, extravascular, and efferent vascular; the relationship determined the existence and extent of the œdema. The total protein content of the extravascular fluid was usually about 0·5%; rarely was it above 1%. The only positive finding which might be of interest was that the albumin-globulin ratio was either high or the same as in the serum. The former was perhaps attributable to imbalance between the afferent vascular and extravascular fluids and the latter to impaired protein reabsorption.

Mr. S. S. ROSE said that soft-tissue radiographs produced a typical pattern depending upon the increase of the fibrous fascial network. Early cases of "lymphœdema" showed a fine "bubble" appearance, which later became a much thicker framework with a much coarser mesh. This change ran parallel to the pitting œdema and the resolution on elevation of the limb—the later cases showing only slight pitting on a solid basis and being only slightly improved by elevation. Œdema of very recent origin—e.g., cardiac œdema—showed only ground-glass opacity. He also referred to a method of investigation of tissue-fluid circulation which he was using—namely, the subcutaneous injection of radio-opaque water-soluble compounds and subsequent serial radiographs to measure the spread.

Mr. PETER MARTIN said that patients treated by the operation which Sir Archibald McIndoe had described did find that the distal parts of the foot swelled as before, but they were grateful because they lost the recurrent attacks of rigor and there was pronounced general improvement. Mr. Martin felt that the tissue had to be excised because the damage was irreversible.

Mr. MICHAEL OLDFIELD said that he treated minor degrees of œdema by using elastic bandages and raising the foot of the bed at night on high blocks. In gross œdema with elephantiasis, the results of Kondoleon's operation were unsatisfactory. He also believed that if skin which was already damaged was used for skin flaps, œdema of the leg recurred. Excision of wide areas of skin-deep and subcutaneous fascia followed by free skin-grafting, produced a very thin leg which was ugly, but the patient could walk on it afterwards.

In his reply, Professor BOYD remarked that Mr. Walker's method of venous-pressure determination was useful and interesting from the research point of view, but for practical purposes the rubber-bandage method was as good as any.

LIVERPOOL MEDICAL INSTITUTION AND *MANCHESTER MEDICAL SOCIETY*

Tumours of Pancreas and Parathyroid

AT a joint meeting on March 2, Prof. JOHN MORLEY spoke on endocrine tumours of the pancreas and parathyroid gland.

Each of 6 patients from whom a single parathyroid adenoma had been successfully removed showed some degree of generalised osteitis fibrosa, though none had urinary calculi or calcification of the kidneys. No fewer than 4 of the 6 patients had an osteoclastoma of the jaw; and such a finding should always be followed by estimation of the serum calcium and phosphorus. In a 7th patient with the characteristic changes in the skeleton and the serum-calcium, no tumour was found, but there might have been one in the anterior mediastinum that escaped detection owing to failure to split the sternum. In the great majority of patients with parathyroid adenoma a single tumour was present; in not more than 6% of cases was there more than one tumour. The tumours occurred much more commonly in the inferior than the superior parathyroids. When not located in the normal position of the parathyroids, the tumours were most commonly found in the anterior mediastinum. They developed at any age; and they were commoner in females than in males in the proportion of 3 to 1. Generalised osteitis fibrosa cystica (often with spontaneous fractures) was the commonest clinical manifestation, but calculi were often found in the urinary tract. The diagnosis was confirmed by a serum-calcium of over 12 mg. per 100 ml. and by a serum-phosphorus reduced below 3·5 mg. per 100 ml.

Professor Morley then described 4 patients from whom he had removed insulin adenomata of the pancreas. In 3 of these patients the tumour was single and small, situated in the tail of the pancreas; in 1 there were five tumours. All were benign. Of the 4 patients, 2 had been diagnosed for some years as epileptic, and in 2 cerebral tumour had been suspected; 2 had on occasion been regarded as suffering from alcoholic intoxication.

In 88% of cases benign insulin adenomata were single, and in 12% multiple. The tumours were found in any part of the pancreas and not predominantly in the tail. Less than 10% of all insulin tumours were malignant. The diagnosis rested on Whipple's triad of symptoms: (1) nervous (or occasionally gastro-intestinal) attacks in the fasting state, (2) a fasting blood-sugar of 50 mg. per 100 ml. or less, and (3) immediate, or almost immediate, relief by injection of glucose. The nervous symptoms consisted of confusion, convulsions, coma, or collapse, and occasionally there were periods of meaningless laughter. These symptoms were apt to bring the patients to neurological or psychiatric clinics, and it was important that those in charge of these clinics should have in mind the possibility of hypoglycæmic manifestations of insulin tumours. The results of operative removal of these tumours were dramatic; and almost always cure was complete.

Reviews of Books

L'organisation des os

P. LACROIX, professeur à la Faculté de Médecine de Louvain. Paris: Masson. 1949. Pp. 228. Fr. 900.

THOSE interested in problems of bone growth will be acquainted with the experimental studies of Professor Lacroix which have been reported in a long series of papers during the last ten years. He has now gathered his results together in a small book, richly illustrated and abundantly annotated with references to the extensive literature of this subject. Of particular interest is the development of osseous tissue at the site of injection of alcoholic extracts of growth-cartilage or of the implantation of fragments of bone which have been killed by immersion in alcohol. Probably, however, these experiments will need to be extended and amplified before their significance can be finally assessed. There is one curious omission in the discussion of the relation of osteoclastic activity to the remodelling process at the metaphyses of growing bones—no reference is anywhere made to the important observations of E. Mellanby on the influence of vitamin A on this process. The practical application of Lacroix's experimental work are everywhere apparent; for this reason it needs to be carefully studied by the orthopædic specialist.

ROYAL SOCIETY OF MEDICINE

Chronic Œdema of the Leg

THE section of surgery met on April 5, with MR. DIGBY CHAMBERLAIN, the president, in the chair, to discuss the treatment of chronic œdema of the leg.

Prof. A. M. BOYD said that from analysis of 673 cases a tentative classification had been adopted: (1) venous, (2) erythrocyanoid, (3) lymphœdematous, and (4) angiomatoid. Mixtures of several types were frequently seen. Venous œdema might be complicated by lymphœdema due to spread of inflammation through the vein walls to the perivenous lymphatic vessels; or erythrocyanosis frigida might be followed later by a "white leg," which in its turn might be complicated by inflammatory œdema. The angiomatoid group were usually seen in the pure state.

Describing the routine investigation of cases at Manchester, Professor Boyd said that patients were photographed, their limb-size was measured, and angiograph and soft-tissue radiographs were taken. Venous pressures were measured by a modification of the method used by Mr. A. J. Walker, of St. Bartholomew's Hospital. There were two basic types of limb: (1) normal arterial circulation (arteries and veins of normal calibre), and (2) erythrocyanoid type (both arteries and veins small—a half or a third of the normal calibre).

The clinical manifestations of the various œdemas depended on the type of limb involved: for example, a "white leg" would show less tendency to resolve if the limb already had a poor blood-supply. The same applied to lymphœdema.

Iliofemoral thrombosis—the typical "white leg"—other than puerperal in origin, was commonly seen over 40 years of age. Apparently spontaneous iliofemoral thrombosis over the age of 60 years was indicative of malignant disease. Deep phlebitis in the calf veins was usually traumatic in origin. Fungus infection was a frequent cause of otherwise unexplained phlebitis.

Certain cases of "lymphœdema of indefinite origin" were probably venous in origin, due to progressive loss of valves in the deep veins. The contribution of the arterial, venous, and lymphatic factors must be assessed in the individual. Treatment of these œdemas consisted in ascertaining and remedying these factors.

Prof. IAN AIRD emphasised the importance, in the treatment of chronic œdema, of appreciating individual differences. He suggested that solid non-pitting œdema was the result of an original pitting œdema, but that not every case of chronic œdema developed into the non-pitting kind. Why some should proceed to the non-pitting state was not understood, but it was known that for solid œdema a high concentration of protein in the œdema fluid was necessary, and this concentration was likely to be highest when there was complete lymphatic obstruction. In the early stages of pitting œdema, conservative measures were probably sufficient. But consideration should be given at an early stage to the cause of the œdema, because some causes lent themselves to additional specific therapy.

Reviewing the types of cases, Professor Aird pointed out that congenital œdema was becoming less frequent, which raised the question whether the diagnosis had been correct. In some cases chronic œdema was associated with congenital auriculo-ventricular fistula. Œdema associated with bone injury usually improved within a year. A succession of attacks of cellulitis might proceed to chronic, non-pitting lymphœdema, which was not due to obstruction of the lymph pathways so much as to the presence of fixed local antibodies in the tissues; in these cases special treatment in the form of chemotherapy and massage had some success. Quincke's disease could also be treated by massage in the acute stage, and by sympathectomy; but recovery often took place spontaneously after a year. Lymphœdema præcox was the most progressive and intractable of all.

Professor Aird said in summary that the best hope of controlling œdema of the leg was still the elastic bandage initially and the elastic stocking later; the stocking should extend to the groin and be supported by a suspender-belt. Solid œdema could be relieved only operatively, by excision in two stages of the subcutaneous layer and the deep fascia. Amputation was much less often necessary for elephantiasis of the leg than of the arm.

Sir ARCHIBALD MCINDOE said that chronic œdema had always been, for the patient, one of the most distressing and disabling conditions, and for the surgeon one of the most disappointing. In tropical climates œdema of the leg might be parasitic in origin; or it might be non-parasitic, due to lymphatic obstruction or other causes.

Listing the types of œdema, Sir Archibald doubted whether Milroy's disease ever occurred outside the famous family which Milroy described. Idiopathic lymphœdema præcox, in adolescent females, was a non-inflammatory condition, probably due to a low-grade inflammatory process. Inflammatory lymphœdema began as an inflammatory attack and spread from the nodal points in the leg, the cause being a streptococcus or a staphylococcus. Secondary lymphœdemas formed a mixed group, covering all other types of œdema. Sir Archibald explained that from his point of view cases of idiopathic lymphœdema præcox and of inflammatory œdema constituted the largest group. With regard to lymphœdema, he felt that undue attention was being given to the venous as opposed to the lymphatic aspect.

Surgical intervention might take the form of reversing the lymph-flow. This had very seldom caused lasting benefit; patients treated in this way needed very careful postoperative elastic bandaging, which they could have had without the operation. The centric obstruction might be traversed by providing a lymphatic bridge—from the leg to the axilla, for instance. This could provide benefit, but it was a difficult and dangerous operation which should only be done by a plastic surgeon.

Sir Archibald described a series of cases in which the lymph-bearing area was removed. The subcutaneous tissue and deep fascia was removed down to the muscle, leaving large skin-flaps no deeper than a Wolfe graft. These dermo-epidermal flaps were then applied. The whole process was carried out at one or more operations. The results were most hopeful, although the operation was only suitable in certain cases. The grafts might act as a strong elastic bandage, or it might be that the removal of the lymphatic tissue was itself curative. The œdema was still left at places where excision could not be done—the toes and the tendo achillis.

Lastly, œdema of the leg was a condition which, in the early stages, should be medically curable, and he looked forward to the time when the inflammatory processes could be brought under control.

Sir HAROLD GILLIES said that the operation of putting a wick across a lymphatic block was the right one where there was a mechanical block, as in lymphœdema præcox and traumatic cases.

Mr. A. J. WALKER described the method of taking venous pressures referred to by Professor Boyd. In this an apparatus was adapted from a sphygmomanometer, with a bottle of fluid and a length of 'Polythene' tube, which was filled with the fluid and inserted into a vein in the foot. The pressure was varied and the point at which blood was seen to flow out into the tube was

THE LANCET

LONDON: SATURDAY, APRIL 29, 1950

Surgical Intervention in Hæmatemesis

In 1935 Gordon-Taylor[1] rendered a service by shattering unwarranted satisfaction with the purely medical management of hæmatemesis. It is easy to understand why at that time surgery was in disrepute; it was demanded only as a last resort, and without blood-transfusions the surgeon's material was a pale corpse, often saline-soaked. Hurst's[2] oft-quoted figure of 4% for the (corrected) case-mortality with medical treatment had encouraged its pursuit. Chiesman[3] had already found that with hæmorrhage recurring within 24 hours of the start of medical treatment the fatality-rate was 74%, and in the Middlesex Hospital series,[4] 1925–35, the rate for such cases was no less than 78%. On the other hand, liberal transfusions and early feeding (Meulengracht[5] and Witts[6]) had begun to increase the safety of medical measures. And it is now clear that after 1935 the pendulum swung too far towards surgery. Finsterer[7] achieved a 5% mortality by operating on every case of massive hæmorrhage in a patient known to have a chronic gastroduodenal ulcer; as he remarked "they needed operation anyhow." Tanner[8] for some five years carried out a similar programme with a mortality of 7% in 110 cases, the average age of the patients who died being 66. But now, like most surgeons in this country, Tanner feels that only in a selected small group of cases is operation necessary. As he says, "it is not the operative mortality that interests us, it is the mortality of hæmatemesis and melæna." Avery Jones's[9] over-all figures (6–7% mortality) confirm the value of this policy. Moreover, he has pointed out,[10] it is the over-70 group, with associated serious medical conditions, that play havoc even with such good statistics. In the 1945–49 period, out of 584 cases in his hospital, only 23 were submitted to emergency surgery, with 4 deaths.

The man under 45 rarely dies from hæmatemesis or melæna: a mass of statistics prove that. Meulengracht[11] had 1031 cases with 26 deaths, only 1 of which was under the age of 40; Tanner has had a consecutive series of 501 with 1 death; Avery Jones records a mortality of 2%. Statistics, however, can be spun too fine, and age is not a reason for ceasing to be alert to the hazard. These figures come from highly specialised clinics, and most surgeons can recall an occasional death in a young patient. Over the age of 45, one or two out of every five patients die from such hæmorrhage, despite massive blood-transfusions and the fullest medical care. The older man dies because he cannot withstand blood-loss well, and because he has a chronic ulcer with the vessel walls fixed, "hard as a quill," unable to retract. Obviously the surgeon's function is to operate only on patients who would otherwise bleed to death. But to know which—aye, there's the rub!

The first essential is a suitable team; "an enthusiastic physician and a reluctant surgeon are the ideal combination" (Lewis[12]). Patients are probably best admitted into medical wards, with an understanding that the surgeon should be invited to see them all within 24 hours of admission. This enriches the surgeon's experience and helps him to appraise the limits of medical measures. The first problem of the physician will be the exclusion of extragastric causes of bleeding—not always easy. In 85% of hæmorrhages gastroduodenal ulceration is responsible, and in deciding for or against operation it should be remembered that the mortality of bleeding from a gastric ulcer is twice as high as that of bleeding from a duodenal ulcer (Avery Jones). The history is of course the most valuable aid in diagnosis; yet it can be misleading. Only in some 60% of massive hæmorrhages is a history of ulcer dyspepsia obtained; with cirrhosis of the liver there is often a dyspeptic story, and indeed often an associated ulcer. Tanner and Avery Jones have advocated the more frequent use of gastroscopy in the doubtful case, but this should normally be practised only by those particularly experienced. American writers think that there is a place for the immediate barium meal, despite its obvious limitations; for the detection of a gastric ulcer may well decide whether operation should be performed or not. But there is evidence that a barium meal may cause bleeding to start again; so it should not be lightly undertaken (Amendola[13]). Meulengracht points out that all his patients who died had hæmatemesis as well as melæna. He holds that with melæna alone it is always justifiable to temporise; for as little as 2 oz. of blood will give a melæna stool.[14] On the other hand in some 60% of cases[15] melæna is but the first sign and the hæmatemesis comes later. Also, as Avery Jones remarks, the very ill patient very often seems too weak to vomit blood. The fact that a melæna is not accompanied by hæmatemesis is therefore no reason for bland optimism. Ulcer pain almost always ceases with the hæmatemesis; its persistence, as Desmond[16] and Avery Jones show, should be seriously viewed as a harbinger of catastrophe. Likewise hæmatemesis during the course of medical treatment is evidence of a progressive burrowing lesion and will usually need surgery for its control.

The question often arises as to whether the hæmorrhage is massive; the loss of a pint of blood is no more than the average blood-donor sustains without any harm. Recurrent syncope is the most valuable single sign of renewed bleeding (Hoerr et al.[17]). In the older patients continued bleeding should always be suspected if the blood-pressure does not rise satisfactorily on repeated transfusion in the first 24 hours (Amendola). The hæmoglobin figure is of some value, even though hæmodilution may not

Neurological Anatomy in relation to Clinical Medicine

A. BRODAL, professor of anatomy, University of Oslo. London: Oxford University Press. 1948. Pp. 496. 42*s.*

Professor Brodal's work in the department of anatomy at Oxford gave him an approach to the nervous system which was as much concerned with function as with structure. His clinical work in the neurological department in Oslo has led him to apply that liberal approach to the understanding of the nervous system in disease. The Oxford schools of anatomy and physiology have always been in the closest way linked with the English school of neurology, and it so happens that neurology in Oslo springs largely from the same source. Add to this Dr. Brodal's lucid and melodious English and the result is this erudite and gracious volume. It is not the book to fly to when a forgotten piece of anatomy crops up in a clinical problem; but it *is* the place to find clearly discussed the present state of understanding of the working of the optic, olfactory, and autonomic systems, to read up the structural basis beneath the rapidly changing research into the function of the cerebellum or the thalamus, and to savour the fruits of a rather more leisurely observation of nervous diseases than is usual with us today. The good student will derive from it new enlightenment and a stimulating outlook; for this is one of those rare anatomical books where facts seem to be less important than thoughts.

Le curare en anesthésie

ERNEST KERN, D.A. Paris: Masson. 1950. Pp. 124. Fr. 300.

Dr. Kern has written an up-to-date and comprehensive little monograph on curare. The material included is already well known to English-speaking anæsthetists and should now be of the greatest use and interest to our French colleagues. Dr. Kern spent a good deal of time in this country when training, and the British viewpoint can clearly be seen throughout the book. The history of curare, with its pharmacology and physiology, is followed by the indications for the use of the drug, which include cæsarean section and tetanus. The choice of which anæsthetic agent to administer in combination with curare is discussed in detail, while the technique of conducting the combined anæsthesia is described in a practical manner. Kern shows his training by stressing the importance of artificial respiration by pulmonary inflation as the essential immediate treatment of overdose. The book closes with an account of the accidents which may follow curarisation, together with a section describing the more recent synthetic substitutes for curare. This book deserves better illustrations than the few very miniature clinical charts.

Vitamin Methods

Vol. I. Editor: Dr. PAUL GYORGY, School of Medicine, University of Pennsylvania. New York: Academic Press. 1950. Pp. 571. $10.

THE experts responsible for the five sections of this book have sought to provide a complete guide to methods of estimating vitamins. There are short historical accounts and critical appraisals of techniques, but the most important part of the book is devoted to descriptions of the methods themselves. The aim has been to make the text self-contained; for, though over 1100 references have been cited, it is intended that workers shall be able to use any of the methods without referring to the original publications. Working directions are therefore extremely detailed, and clearly based on practical experience in the laboratory.

The sections contain more than their short titles might suggest. Thus E. T. Stiller's account of physical methods of vitamin assay, though mainly concerned with ultraviolet absorption spectrometry and fluorometry, also describes fully methods of extraction and separation. Paul György, with S. H. Rubin, deals with chemical methods of assay; and A. Bessey opens his section on microchemical methods for the determination of vitamins in serum and in blood-cells with instructions on the collection of specimens and the construction of pipettes for measuring small volumes. E. E. Snell, writing on microbiological methods, discusses the nutritional requirements of test organisms and gives methods for maintaining stock cultures. In a closing chapter on the use of optical instruments, E. Hirscberg describes the construction and working of most of the commonly used photometers, spectrophotometers, and fluorometers manufactured in America.

This seems to be one of the most complete laboratory manuals of its kind: a vast amount of useful information that has been packed into less than 600 pages.

Physiology in Diseases of the Heart and Lungs

M. D. ALTSCHULE, assistant professor of medicine Harvard Medical School.

BY an error which we much regret, we last week printed under this heading the review of a different book. The proper review will be published shortly.

Proceedings of the Annual Meeting of the British Medical Association, 1949 (London: Butterworth. 1950. Pp. 468. 25*s.*).—The papers given at last year's "Sections," supplemented by brief accounts of the discussions, are here available for those who wish to turn back to them for reference, or refresh their memories of a stimulating occasion.

The World of Learning (London: Europa Publications. 1950. Pp. 881. 60*s.*).—This compilation's third edition in three years contains 12 more pages in the main text than there were in the second edition and 45 pages of an index of institutions (a new feature). It has been impossible to revise the section on China, because postal communication with that country has been cut by the civil war; nor are Ethiopia and Tibet included. Otherwise much useful information seems to be there about educational, scientific, and cultural institutions throughout the world.

Allergy (London: Gollancz. 1950. Pp. 210. 9*s.* 6*d.*).—Dr. Harry Swartz condenses for the lay reader most of the known factors that influence the allergic state. Historically the concept of allergy is shown as an offshoot of immunology. More recently it has been shown that infection in general has an allergic component. Some of the statements made in the book are dogmatic without being correct, and the meaning is not always clear; but the story about the medical officer whom his superior officer thought "was a goldbrick bucking to get out of the combat zone" was full of interest.

The British Encyclopœdia of Medical Practice (London: Butterworth. 1950. *Medical Progress, 1950.* Pp. 524. 32*s.* 6*d.* *Cumulative Supplement, 1950.* Pp. 481. 27*s.* 6*d.*).—In his introduction to *Medical Progress* Lord Horder, editor in chief, gives pride of place to Dr. Philip S. Hench, of the Mayo Clinic, for his work on 'Cortisone,' which is discussed in a critical survey by Dr. D. T. Davies. Other subjects reviewed in this volume include the use of streptomycin, *p*-aminosalicylic acid, and B.C.G. vaccination in tuberculosis, vagotomy for peptic ulcer, sympathectomy in hypertension, the new antibiotics, and the latest news of the hypothalamus. The *Cumulative Supplement* as usual contains short reports on work substantiated since the publication of the original twelve volumes.

Modern Pattern for Marriage. (London: Reinhardt & Evans. 1949. Pp. 110. 8*s.* 6*d.*).—This American book is intended for those about to marry, but seems likely to bore or depress them. Dr. Walter R. Stokes thinks that no girl should marry until dilatation has been performed by the doctor. If by any chance the couple have been so foolish as to marry without consultation, they are advised not to have intercourse during the honeymoon but to wait and see the physician first. (This would have much astonished Uncle Toby.) Dr. Stokes also looks forward to an increase in the practice of surgical sterilisation, on grounds of family health and welfare, and he advocates relaxation of the laws on abortion. Why Mr. David Mace, PH.D., so well known in connection with the Marriage Guidance Council, has chosen to write a foreword to this English edition of the book is something of a mystery.

There are excellent diagrams of sagittal and coronal sections of the sex organs, but they are labelled simply "side and front views." Medical writers seldom realise how confusing, and even frightening, such illustrations are to lay people. If we are to be frank, let us have faithful representations of the external parts, and then try to explain the internal anatomy. Most people seem to think that the vaginal passage runs straight up and down the body—a misapprehension sustained by the usual neat diagrams showing the uterus poised on top of the vagina to such statistics. He need but have a proper pride in the lives he has saved which would otherwise have almost certainly been lost. Life-saving surgery, not the collection of impressive statistics, is his function.

Inoculation and Poliomyelitis

THE observations in Australia[1] and in London[2] which have drawn attention to the association between prophylactic immunisation and paralytic poliomyelitis were discussed at a crowded meeting of the epidemiology and State medicine section of the Royal Society of Medicine on April 21, when Prof. F. M. BURNET, F.R.S., of Melbourne, gave his interpretation of the facts. Dr. W. H. BRADLEY of the Ministry of Health, who presided, took the view that our knowledge is still too incomplete for any precipitate administrative action to be taken at this stage. Professor BURNET contended that MCCLOSKEY had clearly shown in the 1949 epidemic in Victoria that paralytic poliomyelitis in the injected limb occurred within two months of inoculation with pertussis vaccine, either alone or in combination with diphtheria A.P.T., more often than would be expected by chance. Most of the cases of paralysis arose within seven to eleven days of the injection—i.e., within the accepted limits of the usual incubation period of poliomyelitis. The evidence incriminating A.P.T. given by itself was less conclusive, but there was a suggestion of an increased frequency of paralysis in the injected limb five to fourteen days after inoculation with this agent. Subcutaneous or intramuscular injection of these antigens seemed to be followed by a period of heightened vulnerability to the paralytic effects of poliomyelitis in the injected limb, which lasted usually for seven to eleven days but might last up to forty days.

As a self-confessed academically minded virologist, Professor BURNET was interested in the explanation of this association. There were, he thought, four possible hypotheses. The first—contamination of needle or prophylactic agent—could be ruled out with some confidence; the cases had occurred in widely scattered places after injection with different batches of antigen by different physicians whose technique was apparently flawless. A second view, said to be favoured by MCCLOSKEY himself, was that inoculation produced an altered physical reaction to poliomyelitic infection: the inflammatory focus resulting from the injected antigen produces a suitable milieu for the multiplication of the virus which is circulating in the blood during the incubation period of the disease; and the virus then tracks up the neuronal path to the central nervous system to cause the localised paralysis. But there is no good laboratory evidence that viræmia occurs in poliomyelitis or that the virus multiplies in inflamed mesenchyma tissue. A third possibility is that some toxic agent in pertussis vaccine, when deposited in or near a muscle, tracks up the motor nerve rather as does the toxin of tetanus. Professor BURNET thought it curious that the time taken for the postulated toxic agent to ascend the neurone coincided so closely with the incubation period of poliomyelitis: it might be that the toxic inflammatory mass in the limb muscle produces an antigen-antibody reaction which provokes neural lesions in the spinal cord. He evinced no enthusiasm for these suggestions but inclined to the belief that the inflammatory reaction produces fibrosis and scarring which affects the nerve-trunks and increases their vulnerability by producing a reflex neural disturbance in the corresponding region of the spinal cord. The effect, he thought, was analogous to that of severe exercise.

Whatever the theoretical explanation of this association between prophylactic injection and subsequent paralysis, its potential importance undoubtedly calls for much more work in this field. Among other questions which urgently require an answer, Professor BURNET asked whether subcutaneous injections are less likely than intramuscular ones to precipitate paralysis; and whether the alum or other chemicals present in some vaccines are important. Dr. DENNIS GEFFEN, medical officer of health for the metropolitan borough of St. Pancras, then recounted the details of his experience in London in 1948 which has already been noted in these columns.[3] Next Prof. A. BRADFORD HILL, D.SC., outlined the preliminary results of a pilot survey in English sanitary districts, made with Dr. J. KNOWELDEN. In a series of poliomyelitis patients under five years of age they had analysed the distributions of the paralysis and compared those with the sites of inoculation, and they had compared the inoculation history of these children with that of a control series of measles cases notified as residing in the same area at the same time and of the same age and sex. It was clear from the findings that the Australian experience was not unique; once again it was easy to see the concentration of paralysed cases among those most recently inoculated and the election of the injured limb for paralysis. It seems likely that inoculation with an antigen during the early stages of poliomyelitis infection does increase the incidence of paralysis as well as determining its site; but, as Professor BRADFORD HILL was quick to point out, his data gave no guide to the relative risks involved—e.g., as between the different antigens. Dr. GEFFEN and Dr. A. H. GALE made what they regarded as merely educated guesses about the frequency of paralysis among inoculated children, but without extensive field studies no dogmatism is possible. Despite the promising leads given by animal studies, such as Dr. G. M. FINDLAY described, the general feeling at the meeting was that further investigation, both here and in America, must be the ultimate court of appeal.

Further evidence has been provided by MARTIN,[4] who has collected 17 cases of his own, with information on a further 60–70, in which paralysis came on within four weeks of injection into the affected limb. Usually there was unilateral paralysis of the arm muscles supplied by the motor roots of the fifth, sixth, and seventh cervical segments of the spinal cord. MARTIN does not claim that in these cases the diagnosis of poliomyelitis was established; but the accompanying constitutional symptoms, the changes in the cerebrospinal fluid, and the observed seasonal incidence were strong presumptive evidence. There was a clear coincidence in the ebb and flow of these local paralyses and of poliomyelitis over the years since 1941, and even the seasonal and geographical distribution were identical.

be evident for 24 hours. DOUTHWAITE[18] regards a 50% hæmoglobin as a sign of severe hæmorrhage. American writers consider the red-cell count of more value; 3,500,000 or lower denotes a severe bleed. Often patients bleed quietly into the bowel and have lost 2–3 pints before their condition draws attention to the hæmorrhage. Where the surgeon is dallying over surgery, there is something to be said for IVOR LEWIS's advice to have a Ryle tube in position and take samples of gastric contents every half hour. But full stomach washouts seem inadvisable and may restart bleeding; they are advisable only when the patient is too weak to vomit.

To withhold blood-transfusion on the supposition that raising the blood-pressure "blows out" the vessel thrombus is wrong. Some physicians still refrain from giving blood until the hæmoglobin is 40% and the blood-pressure below 100 mm. Hg; but a patient in this state is no longer in a position to withstand a fresh hæmorrhage, which may do irreparable damage to the kidneys, liver, and even the eyes and brain. As COSTELLO[19] points out, massive hæmorrhage may cause death not in a matter of minutes or hours, but days or often weeks after the onset; in 75 fatalities he found that 71 of the patients had received only a moderate fraction of the blood lost. CHURCHILL[20] too has explained that in ulcer hæmorrhages, as in those of battle casualties, late transfusion cannot compensate for the earlier delay. The blood-urea is often held as a warning signal that surgery may be risky. But it often parallels the severity of the bleed, and we know that the high figure is not merely due to blood-protein absorption but is the combined effect of anoxæmia, reduced blood volume, and low blood-pressure. TANNER indeed regards it as an "incentive" to surgery and has operated successfully on patients with blood-ureas of 180–250 mg. per 100 ml.

"No one should operate on hæmatemesis with a mortality of over 5% for cold gastrectomy" (LEWIS). Partial gastrectomy is being regarded more and more as the deliberate surgical plan of attack. It is in fact often an easier operation than the palliative alternatives suggested. With the massive hæmorrhage there is arterial bleeding, and a small erosion may be responsible for a severe loss of blood. This erosion may not be easy to see, and often only the finger within the stomach can feel the bleeding-point, no larger than a mustard seed (BOHN[21]). The high posterior gastric ulcer may feel so soft that it cannot be detected until the stomach has been divided and retracted to the left (IVES[22]). Thus a high gastrectomy will often have to be undertaken, even if the findings are apparently negative. Moreover, palliative vessel ligations are often followed by recurrent bleeding. For the gastric ulcer, a gastrectomy with the ulcer left in situ is the obvious choice. The duodenal ulcer, usually posterior, presents a difficult technical problem, for even in "cold" surgery it may require prolonged, tedious, and quiet surgery. The bleeding site is usually transfixed with deep silk mattresses; but this is ligature in continuity, and recurrent secondary hæmorrhages may follow unless the gastric contents are diverted, preferably by gastrectomy. Division of the duodenum distal to the ulcer, leaving the ulcer bed in situ, will be preferred by those experienced. To permit adequate closure of the duodenum, transection of the pyloric antrum may be necessary. It is the practice of some to core out the mucosa (BANCROFT's procedure), so as to prevent the formation of a gastrojejunal ulcer; but such a stump, particularly in this type of case, may slough and leak. Hence some surgeons prefer merely to suture the pyloric stump, undertaking a second operation six weeks later to remove this and the duodenal-ulcer area—often now a relatively simple matter. The gastrojejunal hæmorrhage is an occasional but rarely fatal problem. Where there is a history of recent diarrhœa, erosion of the colon should be suspected and operation performed, for in this type of case bleeding is often disastrous. A particularly diabolical complication, to be borne in mind in any case of hæmatemesis, is the associated perforation. The ordinary clinical picture is masked and there may be little complaint of pain, the deterioration being attributed to further bleeding.

The golden hours for surgery are the first 48 hours: FINSTERER and GORDON-TAYLOR have strongly emphasised this. "If the surgeon does not operate when he could, he finds himself unable to operate when he would" (LEWISON[23]). Experience does, however, suggest that even a late case should not be denied operation; for with ample blood, and if the blood-pressure has been previously maintained, the surgeon may yet succeed.

The hæmatemesis of cirrhosis should be viewed gravely. At least 80% of the patients are dead within a year from such repeated hæmorrhages,[24] and, as LEARMONTH[25] has noted, they die long before reduction of hepatic function has become a threat to life. Often the diagnosis can be settled only by œsophagoscopy; after such hæmorrhage the spleen is often too soft to feel, and spider telangiectases, liver palms, weight loss, and fœtor oris may not complete the picture. Œsophagoscopy shows active ulceration as the source of the bleeding, and this is a pointer to treatment. Numerous methods have been devised—sclerosant injections, inflated balloons, packing with 'Oxycel' gauze—but none has proved successful. To separate the portal from the azygos system of veins, a number of measures have lately been introduced, and a combination of these seems desirable—ligation of the left gastric pedicle, ligation of the splenic artery, and (as TANNER has suggested) high division of the stomach and resuture to complete the vein transection. In WANGENSTEEN's view,[26] high partial gastrectomy may perhaps be the better additional step. It has the added advantage of diminishing gastric acidity and the tendency to acid peptic erosion of the œsophageal varices.

The proper appreciation of the surgeon's rôle is important: he is not there as a forlorn hope. But with a policy of selective surgical intervention, he must expect high mortality figures, and the measure of his wisdom will often be his professional *amaurosis* to such statistics. He need but have a proper pride in the lives he has saved which would otherwise have almost certainly been lost. Life-saving surgery, not the collection of impressive statistics, is his function.

Inoculation and Poliomyelitis

THE observations in Australia[1] and in London[2] which have drawn attention to the association between prophylactic immunisation and paralytic poliomyelitis were discussed at a crowded meeting of the epidemiology and State medicine section of the Royal Society of Medicine on April 21, when Prof. F. M. BURNET, F.R.S., of Melbourne, gave his interpretation of the facts. Dr. W. H. BRADLEY of the Ministry of Health, who presided, took the view that our knowledge is still too incomplete for any precipitate administrative action to be taken at this stage. Professor BURNET contended that McCLOSKEY had clearly shown in the 1949 epidemic in Victoria that paralytic poliomyelitis in the injected limb occurred within two months of inoculation with pertussis vaccine, either alone or in combination with diphtheria A.P.T., more often than would be expected by chance. Most of the cases of paralysis arose within seven to eleven days of the injection—i.e., within the accepted limits of the usual incubation period of poliomyelitis. The evidence incriminating A.P.T. given by itself was less conclusive, but there was a suggestion of an increased frequency of paralysis in the injected limb five to fourteen days after inoculation with this agent. Subcutaneous or intramuscular injection of these antigens seemed to be followed by a period of heightened vulnerability to the paralytic effects of poliomyelitis in the injected limb, which lasted usually for seven to eleven days but might last up to forty days.

As a self-confessed academically minded virologist, Professor BURNET was interested in the explanation of this association. There were, he thought, four possible hypotheses. The first—contamination of needle or prophylactic agent—could be ruled out with some confidence; the cases had occurred in widely scattered places after injection with different batches of antigen by different physicians whose technique was apparently flawless. A second view, said to be favoured by McCLOSKEY himself, was that inoculation produced an altered physical reaction to poliomyelitic infection: the inflammatory focus resulting from the injected antigen produces a suitable milieu for the multiplication of the virus which is circulating in the blood during the incubation period of the disease; and the virus then tracks up the neuronal path to the central nervous system to cause the localised paralysis. But there is no good laboratory evidence that viræmia occurs in poliomyelitis or that the virus multiplies in inflamed mesenchyma tissue. A third possibility is that some toxic agent in pertussis vaccine, when deposited in or near a muscle, tracks up the motor nerve rather as does the toxin of tetanus. Professor BURNET thought it curious that the time taken for the postulated toxic agent to ascend the neurone coincided so closely with the incubation period of poliomyelitis; it might be that the toxic inflammatory mass in the limb muscle produces an antigen-antibody reaction which provokes nerlau lesions in the spinal cord. He evinced no enthusiasm for these suggestions but inclined to the belief that the inflammatory reaction produces fibrosis and scarring which affects the nerve-trunks and increases their vulnerability by producing a reflex neural disturbance in the corresponding region of the spinal cord. The effect, he thought, was analogous to that of severe exercise.

Whatever the theoretical explanation of this association between prophylactic injection and subsequent paralysis, its potential importance undoubtedly calls for much more work in this field. Among other questions which urgently require an answer, Professor BURNET asked whether subcutaneous injections are less likely than intramuscular ones to precipitate paralysis; and whether the alum or other chemicals present in some vaccines are important. Dr. DENNIS GEFFEN, medical officer of health for the metropolitan borough of St. Pancras, then recounted the details of his experience in London in 1948 which has already been noted in these columns.[3] Next Prof. A. BRADFORD HILL, D.SC., outlined the preliminary results of a pilot survey in English sanitary districts, made with Dr. J. KNOWELDEN. In a series of poliomyelitis patients under five years of age they had analysed the distributions of the paralysis and compared those with the sites of inoculation, and they had compared the inoculation history of these children with that of a control series of measles cases notified as residing in the same area at the same time and of the same age and sex. It was clear from the findings that the Australian experience was not unique; once again it was easy to see the concentration of paralysed cases among those most recently inoculated and the election of the injured limb for paralysis. It seems likely that inoculation with an antigen during the early stages of poliomyelitis infection does increase the incidence of paralysis as well as determining its site; but, as Professor BRADFORD HILL was quick to point out, his data gave no guide to the relative risks involved—e.g., as between the different antigens. Dr. GEFFEN and Dr. A. H. GALE made what they regarded as merely educated guesses about the frequency of paralysis among inoculated children, but without extensive field studies no dogmatism is possible. Despite the promising leads given by animal studies, such as Dr. G. M. FINDLAY described, the general feeling at the meeting was that further investigation, both here and in America, must be the ultimate court of appeal.

Further evidence has been provided by MARTIN,[4] who has collected 17 cases of his own, with information on a further 60–70, in which paralysis came on within four weeks of injection into the affected limb. Usually there was unilateral paralysis of the arm muscles supplied by the motor roots of the fifth, sixth, and seventh cervical segments of the spinal cord. MARTIN does not claim that in these cases the diagnosis of poliomyelitis was established; but the accompanying constitutional symptoms, the changes in the cerebrospinal fluid, and the observed seasonal incidence were strong presumptive evidence. There was a clear coincidence in the ebb and flow of these local paralyses and of poliomyelitis over the years since 1941, and even the seasonal and geographical distribution were identical.

occurred when hexobarbitone ('Evipan') was used instead of pentobarbitone. It seems, too, that intermediate products of glucose metabolism, such as hexose diphosphate, pyruvate, succinate, and fumarate, as well as others, had the same action as glucose, some even more strongly. Sucrose, on the other hand, was inactive.

These observations have not been confirmed in man, but no doubt some evidence will soon be forthcoming. If in fact glucose has this potentiating effect in patients who are recovering from anæsthetics like thiopentone and hexobarbitone, then caution will have to be exercised in the use of intravenous glucose drips during barbiturate anæsthesia or in the immediate postoperative period.

CORTISONE AND A.C.T.H. IN PERIARTERITIS NODOSA

Now that 'Cortisone' and the adrenocorticotropic hormone (A.C.T.H.) have been shown to exert an effect on rheumatoid arthritis and, to a lesser extent, on rheumatic fever, attention is turning to the investigation of these substances in other collagen-vascular diseases—a group which includes periarteritis nodosa, disseminated lupus erythematosus, and anyhow some instances of clinical dermatomyositis. It is now clear that in periarteritis nodosa the effect is profound.

At Johns Hopkins University, Berthrong and his colleagues[1] have shown experimentally that A.C.T.H. can prevent vascular lesions which would otherwise appear after sensitisation. Of 40 rabbits sensitised with horse-serum, half were used as controls and the other half were treated with A.C.T.H. Well-marked vascular and/or cardiac lesions appeared in 18 of the 20 controls, but in only 5 of the 20 animals receiving A.C.T.H. The influence of these hormones on established periarteritis nodosa has been studied clinically at the Mayo Clinic where Shick and his fellow-workers[2] have treated 5 confirmed cases of periarteritis nodosa and 2 of cranial arteritis. In each, prompt subjective improvement ensued, with subsidence of fever in 24–72 hours and a more gradual return to normal of the erythrocyte-sedimentation rate. Partial relapse followed withdrawal of the hormone, with subsequent improvement when treatment was resumed. Of the 5 cases of periarteritis nodosa, 3 were critically ill when treatment (with cortisone) was started; and, despite initial improvement, 2 died in cardiac and renal failure. Necropsy showed complete healing of all arterial lesions; but in the process of healing, fibrous obliteration of the vascular lumens had taken place, with resulting widespread visceral infarction. The adrenal glands of the patient who received the larger amount of cortisone (13·35 g. in 146 days) were atrophied. In most of the patients evidence of hypercortisonism developed during treatment; in the 2 who died there were profound disturbances of plasma electrolytes after lengthy administration of cortisone, but whether this complication was attributable mainly to the hormone or to the antecedent renal disease was uncertain. Together, these two reports encourage the hope that, at least in early cases, cortisone and A.C.T.H. may take an important place in the treatment of periarteritis nodosa.

Cortisone may, it seems, become more plentiful; and in the U.S.A. the price of A.C.T.H. is coming down. At the meeting of the Federation of American Societies for Experimental Biology in Atlantic City last week, Dr. Kenneth Savard and his colleagues at the research division of Cleveland Clinic Foundation reported that ox adrenal-gland extracts retained the enzymes through which cortisone is composed; and that with these enzymes 'Compound F' had been constituted from an inert substance originally derived from soya beans. (Compound F is the principal type of cortisone believed to be secreted by the adrenals in man; but from animal sources it is obtained in smaller amounts than is Compound E, which is also more easily synthesised.) This development is reported in the *New York Times* of April 22, which adds that Messrs. Armour & Co. are reducing the price of A.C.T.H. from $210 per g. to about $100 per g. The company's president has announced that his company has increased production of A.C.T.H. by 30 times in the past year, and is now obtaining almost four times as much of the drug from the same quantity of glands as it did last summer. "Within four or five months we confidently expect to triple the current rate of production"; and he believed that in a few weeks all (American) hospitals equipped to administer the drug safely could be supplied. Work had started on an inhibiting solution that would prolong the action of A.C.T.H.

ADVENTURES AMONG VIRUSES

THE title of the Dunham lectures for 1949, "Adventures among Viruses," gave Dr. C. H. Andrewes, F.R.S., full scope for surveys of the properties of viruses, of influenza, and of the common cold.[1] Viruses, he said, need three properties if they are to be successful parasites—they must be able to multiply, to be transmitted from host to host, and to persist in between. Their urge to multiply involves them in possible trouble at the portal of entry to the host, or at the surface of the cell, or with biochemical conditions inside the cell, and these circumstances may be responsible for the host's ability to resist virus attack in numerous non-specific ways, as Findlay[2] has reminded us. The virus often persists outside the host, in dried crusts or secretions or in the bodies of insect vectors, but latent infection inside the host's body is often important, and latent virus may even be passed from mother or father to offspring, as in the case of the Bittner virus of mammary carcinoma, sheep "scrapie," or mouse choriomeningitis. Jolts which disturb the delicate host-virus equilibrium of latent infection produce clinical signs of disease, as is seen in herpes and possibly in the common cold, and may in fact range from a mild febrile disturbance to an upset as severe as anaphylactic shock.

In dealing with influenza Andrewes turned from the virus to the host-virus interaction in epidemics and pandemics, viewing the problems of the survival of virus and the build-up of epidemics against the background of recent studies of viruses by the World Influenza Centre at Hampstead. Magrassi's observations on the origin of the Sardinian outbreak of 1948, which preceded the Western European epidemic of 1948–49, are particularly interesting in their suggestion of a simultaneous uprising of virus in several village communities, and Andrewes recalled an earlier theory of his own[3] of the evolution of an influenza virus from a basic strain to an epidemic variant. Such a mechanism would explain what Andrewes calls the slow-fuse phase preceding an epidemic, though mutation through several stages is needed to explain pandemics such as the influenza one of 1918.

His third lecture, on the common cold, was largely an account of the work of the research unit at Salisbury which has been described elsewhere,[4] though Andrewes added some tit-bits concerning growth of virus in tissue cultures of human embryo material and the effect of chills on experimental colds. This particular adventure seems likely to lead to long-overdue additions to our knowledge of the epidemiology of the cold, and it will not be surprising if some future annotation describes

Annotations

CANCER RESEARCH ON A BROAD FRONT

A WIDE variety of investigations, both complete and in progress, is recorded in the 47th annual report of the Imperial Cancer Research Fund. Some ventures into the realm of hypothesis are also disclosed, indicating an intensification of the attack on chemical aspects of the cancer problem. There is hope, no doubt, that these may succeed where others have reached an impasse.

Promising results have already been attained by Mr. H. G. Crabtree while using six deliberately chosen isomeric aminoazotolenes to determine their carcinogenic properties in rat livers. Contrary to a previous suggestion that some parallelism exists between carcinogenic potency and liberation of the diamine of certain azo- compounds, Crabtree draws attention to some discrepancies in such a correlation. The carcinogenic potency of three isomeric methyl derivatives of "butter yellow," for example, vary, though all three would yield the same diamine. One isomer equals in potency the parent compound, another has moderate carcinogenic action, while the third is almost ineffective in inducing liver cancer. This conspicuous difference between observed fact and current explanation led to an experimental examination of the properties of the "other half" of the split azo- molecule. The conclusion was reached that the monoamine portion of the reduced azo- compound plays an active part in determining cancer production. There emerged also the observation that azo- compounds capable of forming *p*-toluidine by reductive fission lack carcinogenic power and behave as stimulators of normal growth. Conversely, those liberating o-toluidine are carcinogenic and do not influence body growth. Crabtree unites his new observations in one tentative explanation. Appropriate diamines (or their oxidation products), arising from the reductive fission of azo- compounds, may interfere with the function of enzymes concerned with folic-acid synthesis, thus providing in the liver the initial derangement of function for the subsequent induction of tumours. If the azo-compound is potentially capable of liberating *p*-toluidine, the precursor of *p*-aminobenzoic acid, this process is antagonised by compensatory production of folic acid, which preserves a physiological normality in liver cells and permits normal growth, with the biological consequence of preventing the emergence of cancer. Thus *the first stage of the cancer process rather than the* end-result of established disease is being analysed. It has provided valuable data and inspired further effort.

The progressive nature of tumour behaviour is again emphasised by Dr. L. Foulds who last year illustrated this characteristic from a wealth of mammary growths in mice and now adds to them supporting evidence from the experiences of transplantation of an induced bladder tumour. In the course of serial transplantation of a single tumour of the bladder, different stages of progression from localised papilloma through intermediate mixed forms to disseminating undifferentiated carcinoma were seen. These observations correspond with that of von Hansemann in human pathology of the somewhat rare phenomenon of true anaplasia. Manipulation of experimental material has enabled Dr. Foulds to enunciate certain principles or rates of tumour progression.

Contributions to the study of mouse mammary tumours, unaccompanied by Bittner's agent, are being made by Dr. B. D. Pullinger. Dr. Vazquez-Lopez and Mr. P. Williams have attempted to induce gastric tumours in rats by combining local damage by hormone (posterior pituitary extract) with a known carcinogen, acetyl-amino-fluorene. Mr. Williams is investigating œstrogen sensitivity in some pure-line strains of mice.

Dr. James Craigie, F.R.S., who has succeeded Prof. W. E. Gye, F.R.S., as director, is studying intensively isolated surviving malignant cells. Optical methods are being explored to seek reliable criteria of cell death and cell survival. Phase-contrast and also ultraviolet microscopy and photography, to which Mr. J. R. Ludford, D.SC., has also contributed, offer some promise of extending knowledge of the cytology of living tumour cells. Quantitative data concerning viability of tumour cells under various conditions is being gathered and permanently recorded. An artificial intracellular fluid has been devised as a standard for suspension of all cells undergoing test. It resembles the analysis of intracellular muscle fluid with the addition of a succinate as organic ion. These studies are regarded by Dr. Craigie as prerequisite to any further attempts to detect virus in dried tumour material.

The claim, made and widely accepted a year ago,[1,2] to have transmitted tumours by means of virus contained in an inoculum of cells dried to an unmeasured degree appears to have been insecurely founded. No control tests that might have excluded the presence of viable cells among the dextrose-treated dried cells were recorded at that time. It appeared later that similarly dried mammary tumours had also been transmitted.[3] These epithelial tumours grew at the point of inoculation in subcutaneous tissue in both male and female mice. The implication of this result in male mice was either that the epithelial cells were still viable, notwithstanding freezing and drying, or (seeing that a tumour arose at the point of inoculation) that the inoculum coincided with a mammary rudiment. The epithelial cells of the rudiment in the latter case then became infected and were stimulated to tumour growth by a variant of the Bittner agent. This variant would have to possess properties of action far more rapid than the agent we know and would also have to be independent of ovarian hormone, another novel feature. The first interpretation, that sometimes cells survived, was the obvious one, but the second might have been tenable had it in turn been subjected to a control test. A control test would have placed the inoculum outside the mammary fat pads—discrete anatomical structures in which alone mammary glands and mammary rudiments are lodged. Had a mammary tumour developed at the point of inoculation at a distance from any of these pads, it would have provided certain evidence of viability of epithelial cells and, by analogy, of sarcoma cells also. Had no tumours ever developed at the point of inoculation outside fat pads, but only when placed within them, the claims made would have had some support. On the evidence available the virus theory of tumour causation stands where it did after Bittner's discovery of the milk factor.

POTENTIATION OF BARBITURATE ANÆSTHESIA BY GLUCOSE

A SOMEWHAT alarming effect of glucose on barbiturate anæsthesia is described by Lamson and colleagues,[4] who discovered accidentally that if an intravenous injection of glucose was given to a dog recovering from pentobarbitone anæsthesia it sent him back into deep sleep exactly as though he had been re-anæsthetised. If the glucose injection was repeated when the dog again showed signs of recovery the same thing happened; the dog immediately lapsed into deep sleep. However, the cycle of sleep, awakening, glucose injection, and further sleep gradually became shorter until finally the glucose had no further effect, the animal remaining awake and, if anything, hyperexcitable. The same cycle of events

occurred when hexobarbitone ('Evipan') was used instead of pentobarbitone. It seems, too, that intermediate products of glucose metabolism, such as hexose diphosphate, pyruvate, succinate, and fumarate, as well as others, had the same action as glucose, some even more strongly. Sucrose, on the other hand, was inactive.

These observations have not been confirmed in man, but no doubt some evidence will soon be forthcoming. If in fact glucose has this potentiating effect in patients who are recovering from anæsthetics like thiopentone and hexobarbitone, then caution will have to be exercised in the use of intravenous glucose drips during barbiturate anæsthesia or in the immediate postoperative period.

CORTISONE AND A.C.T.H. IN PERIARTERITIS NODOSA

Now that 'Cortisone' and the adrenocorticotropic hormone (A.C.T.H.) have been shown to exert an effect on rheumatoid arthritis and, to a lesser extent, on rheumatic fever, attention is turning to the investigation of these substances in other collagen-vascular diseases—a group which includes periarteritis nodosa, disseminated lupus erythematosus, and anyhow some instances of clinical dermatomyositis. It is now clear that in periarteritis nodosa the effect is profound.

At Johns Hopkins University, Berthrong and his colleagues[1] have shown experimentally that A.C.T.H. can prevent vascular lesions which would otherwise appear after sensitisation. Of 40 rabbits sensitised with horse-serum, half were used as controls and the other half were treated with A.C.T.H. Well-marked vascular and/or cardiac lesions appeared in 18 of the 20 controls, but in only 5 of the 20 animals receiving A.C.T.H. The influence of these hormones on established periarteritis nodosa has been studied clinically at the Mayo Clinic where Shick and his fellow-workers[2] have treated 5 confirmed cases of periarteritis nodosa and 2 of cranial arteritis. In each, prompt subjective improvement ensued, with subsidence of fever in 24–72 hours and a more gradual return to normal of the erythrocyte-sedimentation rate. Partial relapse followed withdrawal of the hormone, with subsequent improvement when treatment was resumed. Of the 5 cases of periarteritis nodosa, 3 were critically ill when treatment (with cortisone) was started; and, despite initial improvement, 2 died in cardiac and renal failure. Necropsy showed complete healing of all arterial lesions; but in the process of healing, fibrous obliteration of the vascular lumens had taken place, with resulting widespread visceral infarction. The adrenal glands of the patient who received the larger amount of cortisone (13·35 g. in 146 days) were atrophied. In most of the patients evidence of hypercortisonism developed during treatment; in the 2 who died there were profound disturbances of plasma electrolytes after lengthy administration of cortisone, but whether this complication was attributable mainly to the hormone or to the antecedent renal disease was uncertain. Together, these two reports encourage the hope that, at least in early cases, cortisone and A.C.T.H. may take an important place in the treatment of periarteritis nodosa.

Cortisone may, it seems, become more plentiful; and in the U.S.A. the price of A.C.T.H. is coming down. At the meeting of the Federation of American Societies for Experimental Biology in Atlantic City last week, Dr. Kenneth Savard and his colleagues at the research division of Cleveland Clinic Foundation reported that ox adrenal-gland extracts retained the enzymes through which cortisone is composed; and that with these enzymes 'Compound F' had been constituted from an inert substance originally derived from soya beans. (Compound F is the principal type of cortisone believed to be secreted by the adrenals in man; but from animal sources it is obtained in smaller amounts than is Compound E, which is also more easily synthesised.) This development is reported in the *New York Times* of April 22, which adds that Messrs. Armour & Co. are reducing the price of A.C.T.H. from $210 per g. to about $100 per g. The company's president has announced that his company has increased production of A.C.T.H. by 30 times in the past year, and is now obtaining almost four times as much of the drug from the same quantity of glands as it did last summer. "Within four or five months we confidently expect to triple the current rate of production"; and he believed that in a few weeks all (American) hospitals equipped to administer the drug safely could be supplied. Work had started on an inhibiting solution that would prolong the action of A.C.T.H.

ADVENTURES AMONG VIRUSES

THE title of the Dunham lectures for 1949, "Adventures among Viruses," gave Dr. C. H. Andrewes, F.R.S., full scope for surveys of the properties of viruses, of influenza, and of the common cold.[1] Viruses, he said, need three properties if they are to be successful parasites—they must be able to multiply, to be transmitted from host to host, and to persist in between. Their urge to multiply involves them in possible trouble at the portal of entry to the host, or at the surface of the cell, or with biochemical conditions inside the cell, and these circumstances may be responsible for the host's ability to resist virus attack in numerous non-specific ways, as Findlay[2] has reminded us. The virus often persists outside the host, in dried crusts or secretions or in the bodies of insect vectors, but latent infection inside the host's body is often important, and latent virus may even be passed from mother or father to offspring, as in the case of the Bittner virus of mammary carcinoma, sheep "scrapie," or mouse choriomeningitis. Jolts which disturb the delicate host-virus equilibrium of latent infection produce clinical signs of disease, as is seen in herpes and possibly in the common cold, and may in fact range from a mild febrile disturbance to an upset as severe as anaphylactic shock.

In dealing with influenza Andrewes turned from the virus to the host-virus interaction in epidemics and pandemics, viewing the problems of the survival of virus and the build-up of epidemics against the background of recent studies of viruses by the World Influenza Centre at Hampstead. Magrassi's observations on the origin of the Sardinian outbreak of 1948, which preceded the Western European epidemic of 1948–49, are particularly interesting in their suggestion of a simultaneous uprising of virus in several village communities, and Andrewes recalled an earlier theory of his own[3] of the evolution of an influenza virus from a basic strain to an epidemic variant. Such a mechanism would explain what Andrewes calls the slow-fuse phase preceding an epidemic, though mutation through several stages is needed to explain pandemics such as the influenza one of 1918.

His third lecture, on the common cold, was largely an account of the work of the research unit at Salisbury which has been described elsewhere,[4] though Andrewes added some tit-bits concerning growth of virus in tissue cultures of human embryo material and the effect of chills on experimental colds. This particular adventure seems likely to lead to long-overdue additions to our knowledge of the epidemiology of the cold, and it will not be surprising if some future annotation describes

studies in remote island communities. Immunity in the case of influenza is often broken down by new antigenic variants, though the experience recorded by Sigel[5] suggests that, even with the same antigenic strain of virus, immunity may have petered out by two years after the original infection. Immunity to colds may be kept up by constant interchange of infection only to suffer defeat if a new variant strain arises, possibly by some such process as the genetic recombination described by Hershey and Rotman[6] and Luria and Dulbecco[7] in plant viruses. Viruses are certainly venturesome creatures and no student of them can lack the spirit of adventure well personified by Andrewes himself.

RESEARCH ON DRUG-ADDICTION

THOSE who study drug-addiction are never likely to be gravelled for lack of matter; for as soon as the behaviour of one drug and its addicts has been thoroughly investigated, a whole host of new substances are already crying out for attention. The World Health Organisation's expert committee on drugs liable to produce addiction,[8] say that, apart from sporadic investigations, the only medical research on drug addiction of which they are aware is being carried out by the United States Public Health Service, and by groups of investigators in South America; and they recommend that governments should be urged to consider whether it would be feasible to start or extend research of this kind. One promising line of research is foreshadowed in their report. They think that a particular arrangement of atoms in the molecule is probably responsible for the addiction-producing power of a drug; and this is supported by the fact that certain drugs which have, in the main, a common structure tend to produce a similar addiction. They argue that other substances with a similar structure should be suspect. The relation of chemical structure to addiction-producing properties should therefore be studied. They also emphasise that any drug which will adequately replace a drug which has produced an addiction must itself be regarded as capable of producing an addiction: that at least is what the available evidence suggests.

Study of addiction is in any case not particularly easy, and a note on chronic barbiturate intoxication, based on the work of Dr. H. Isbell, of the U.S. Public Health Service hospital at Lexington, and published as an appendix to the report, indicates what the difficulties may be—not only for the investigator but for the subjects. It seems that this form of addiction is causing growing concern in America. The production of barbiturates has increased, and is now thought greatly to exceed the amount needed for medical purposes. Since 1940 more and more morphine addicts who are also taking large doses of barbiturates have been admitted to the hospital at Lexington; and on abrupt withdrawal of these barbiturates, or even reduction to less than half the dose, they often developed convulsions or psychotic symptoms, or both. But since these were cases of mixed addiction the direct relation of the withdrawal symptoms to the barbiturates could not be defined. A controlled experiment was therefore undertaken on people whose neurological and psychological state was known; these were five volunteers, all of whom had formerly been morphine addicts. They were given large amounts of barbiturates for 92–144 days and then the drugs were abruptly withdrawn. Their symptoms during the phase of chronic intoxication resembled alcoholism; their mental ability was impaired; they were confused, emotionally labile, dysarthric, and ataxic; and they showed regression. After abrupt withdrawal they all developed abstinence symptoms. The signs of intoxication disappeared and were replaced by weakness, tremor, anxiety, anorexia, nausea and vomiting, rapid loss of weight, rapid pulse and respiration, fever, rise of blood-pressure, cardiovascular instability on standing up, convulsions (in all but one), and psychotic symptoms (in all but one, but not the same one). The psychosis resembled delirium tremens, the patients displaying anxiety, insomnia, confusion, agitation, disorientation, delusions, and hallucinations. Recovery, however, was complete, and no evidence of permanent damage was found 60 days after withdrawal. During intoxication the amplitude of all electro-encephalographic waves increased, and during withdrawal there were bursts of high-amplitude waves and the records during and after convulsions were similar to those found in grand mal; but the pattern returned within 30 days to that seen before the barbiturates had been given. The courage of these volunteers commands admiration; but perhaps neither they nor the investigators realised what they were in for.

CUTS FOR DENTISTS AND PHARMACISTS

LAST June the gross earnings of dentists in the National Health Service were reduced by 20%; and the Ministry of Health has now announced that a further 10% reduction is to be made on May 1. The representative board of the British Dental Association, when it met at the end of last week, protested that this action was arbitrary, and resolved that under existing conditions no useful purpose could be served in continuing negotiations on pay with the Ministry of Health. Presuming the expenses to have remained constant (52% was the proportion accepted by the Spens Committee and in subsequent negotiations), then whereas only a year ago the dentist retained £48 net out of every £100 gross, he will now, it seems, have only £20 for the same work. The dental organisations calculate that the rate of remuneration is in fact down almost to that offered under National Health Insurance; and it is thought that some dentists may turn once again to private practice. In this latest cut, says a spokesman of the British Dental Association, the majority of dentists are being penalised for the behaviour of the few who, by working unduly long hours or giving hasty treatment, have gained remuneration above the Spens scale. Now, it is reasoned, the majority will have to earn a larger number of fees in order to keep their net remuneration anywhere within the Spens scale. The corollaries are that the general standard of work may suffer, and that the Ministry, finding that it is saving much less than the anticipated 10%, will be tempted to make a further cut. Why not, it is asked, impose a ceiling to remuneration, or else a sliding scale of fees, to cut short the activities of the minority, rather than hit at the whole profession?

Another group who have had a cut imposed are the pharmacists. The Chemists' Contractors' Committee have been informed that from May 1 the "on cost" allowance will be reduced from 33 to 16%. (This allowance is the addition made, in remunerating pharmacists, to the wholesale cost of drugs, preparations, and appliances.) This action, the Ministry explains, is being taken because of the delays which might arise in the Whitley Council negotiations; but if agreement is reached on the Whitley Council, or, failing that, if an arbitrator awards a different percentage, that different percentage will apply from May 1.

Prof. A. B. APPLETON died on April 22 at St. Thomas's Hospital, London, where he held the university chair of anatomy. He was 61.

THE death is also announced of Sir ARTHUR ROBINSON, G.C.B., who in 1920 succeeded Sir Robert Morant as permanent secretary to the Ministry of Health and held that office till 1935.

HOSPITAL EXPENDITURE

NEW CHECKS AND CONTROLS

THE Minister of Health has addressed to hospital authorities the following memorandum on their expenditure:

As will be known from statements made in the House of Commons and elsewhere, the Government is deeply concerned at the rapid increase in expenditure on the National Health Service in relation to the national economy as a whole. In 1950–51 the estimated gross expenditure of hospital boards at £244 million is 45% above the level of actual expenditure in 1948–49; of this total £36·2 million represents expenditure by the boards of governors of teaching hospitals—a rise of 46% on 1948–49.

It is fully realised that the rise in expenditure is due to many factors, some outside the control of boards and committees themselves, and is in no sense a reflection of extravagance or waste on the part of hospital authorities. Essential increases have been made in nursing and other staff salaries; the level of remuneration of medical and dental staff has been fixed for the first time on a national basis: costs of some consumable goods have risen; essential improvements have been made in hospital standards and long-standing arrears in maintenance have been met; unstaffed beds have been reopened as the recruitment of nurses and domestics has improved. All these steps have been not only justifiable but unavoidable if a proper service was to be provided.

It is, however, the considered view of the Government that expenditure has now reached a level which must not be exceeded. Consequently, boards and committees must regard their estimates for 1950–51, so far as they are approved by the Minister or the regional board as the case may be, as their final totals of expenditure for the year—which will not be supplemented. Boards and committees should from the outset conduct their administration on the basis that all maintenance costs arising during the year, including all improvements, staff increases, rises in costs of consumable goods, &c., must be met within their approved estimates and that no supplementary estimate will be available; similarly, all capital expenditure required must be met within the approved capital estimate. This clearly requires that a careful and prudent view should be taken of the possibility of improvements or developments during the year, and that no commitment should be entered into which cannot plainly be met without exceeding the estimate for the sub-heads of expenditure affected.

RUNNING CHECK ON EXPENDITURE

If expenditure is to be kept within the estimate a close and continuous watch must be kept on it, and immediate steps taken at the first sign of possible overspending. It has therefore been decided that the following procedure should be adopted:

Hospital Management Committees

(i) A monthly statement is to be prepared by each management committee as soon as possible after the end of each month, showing under each sub-head used for approval purposes (Regulation 9 of the Hospital Accounts and Financial Provisions Regulations, 1948,—S.I. 1948, no. 1414): (a) the total of cash payments made and bills incurred but not yet paid during the preceding month, and the cumulative total up to the end of that month, together with comparable figures of the estimates themselves; (b) a statement of any commitments entered into under each sub-head which may lead to the estimate under that sub-head being exceeded.

(ii) This statement is to be sent to the regional hospital board as soon as possible after the end of each month, with any comments the management committee may wish to make, and a copy of the statement simultaneously sent to the Minister.

Regional Hospital Boards

(i) A monthly statement covering the board's own expenditure is to be prepared and sent to the Minister . . . as soon as possible after the end of each month, together with a statement of action taken to reduce the rate of expenditure if necessary.

(ii) The board is to examine the statements sent to them by management committees each month, make such inquiries and give such direction as may be necessary to reduce the rate of expenditure, and within 14 days of the receipt of each statement report to the Minister on any case in which it appears that there is a danger of exceeding the approved estimate and on the steps taken to prevent this happening.

Boards of Governors

A monthly statement is to be prepared by each board on the same lines as that prepared by management committees and sent direct to the Minister . . . as soon as possible after the end of each month, together with a report in any case where it appears that there is a danger of exceeding the approved estimate stating the action taken to prevent this happening.

On receipt of the above reports from regional boards and boards of governors (or in any other case where action appears to him necessary) the Minister will, if necessary, arrange for immediate inquiries by his officers to determine whether any further steps should be taken.

LIAISON WITH THE DEPARTMENT

It will clearly assist both the Minister and boards and committees in keeping a close watch on expenditure if the Minister is in constant touch with the work of boards and committees as it proceeds. It has therefore been decided that for liaison purposes arrangements should be made for the principal regional officers of the Ministry, or their deputies, to be kept informed of the proceedings of boards and committees by receiving regularly copies of the agenda, papers, and minutes of all meetings of regional boards, boards of governors and hospital management committees (but not of committees or subcommittees unless they ask for these), and by attending such meetings as appears to them desirable. Accordingly, boards and committees are asked to arrange for the above documents for all their meetings held after the date of this memorandum to be sent to the officers indicated in the appendix.

THE TUBERCULOSIS SERVICE

SIX people recently died of smallpox in Glasgow, and considerable discussion has gone on about it since; in the same month 100 people in Glasgow died of tuberculosis, and probably about 1000 contracted it in the same time—without exciting any remark. Dr. HORACE JOULES, speaking on April 22, at a conference arranged by the Socialist Medical Association, used this example to illustrate our habitual neglect of the tuberculosis problem. The meeting was composed largely of delegates from trade unions and other organisations, and the chair was taken by Mr. SOMERVILLE HASTINGS, F.R.C.S., M.P.

Dr. JOULES insisted, as many have done lately, that the general and teaching hospitals are not playing their full part in providing treatment for tuberculous patients. It is a point of honour with such hospitals, he said, to admit every treatable case of cancer within a week; but they have no beds for patients with early and treatable tuberculosis, whose risk to life may be just as serious and urgent. He believes that these hospitals should set aside 10% of their beds for tuberculous cases, but he is not for compelling them to do so: we should try persuasion first, and we must not be put off, he said, by arguments about the balance of teaching for medical students. There can be no more urgent or important study than tuberculosis for the medical student or the student nurse; and at present they are not taught and inspired about it. Of course, they must be protected: patients with tuberculosis must be transferred to a special ward, and nursed only by those who have a resistance to the infection; and nurses and students must be taught proper precautions. These

are the measures taken in the Central Middlesex Hospital, of which he is medical superintendent; and he hopes to be able to show that there is no greater incidence of tuberculosis among the nurses in his general wards than among girls in the general population. He warns prospective nurses and their parents that they will be expected to nurse tuberculosis, and has never found this to have a detrimental effect on recruitment. Sanatoria, however, are hard put to it to get nurses. He mentioned a tuberculosis hospital of 760 beds in the Metropolitan area: half the beds are closed, and to staff the remainder the hospital has only a third the number of trained nurses and a seventh the number of students, per 100 beds, to be found in any major general hospital. These general hospitals, so lavishly staffed in comparison, should not have the right to second to sanatoria patients whom they will not nurse themselves.

Dr. C. H. C. TOUSSAINT, chest physician to the Central Middlesex Hospital, noted that the incidence of tuberculosis among nurses there is far lower than that in any hospital investigated by the Prophit survey. He described three typical cases to show the advantages of combined hospital and domiciliary treatment: all were early cases in young people, all were admitted the day after he first saw them, all were sputum-negative within 2–3 months, and all went home for continued bed rest after a few weeks in hospital. Two are back in full work, less than a year after the onset, and the third—a boy of 15—was admitted with pneumonic tuberculosis last December and sent home sputum-negative and with a rising weight two months later. These case-histories reinforced a remark of Dr. Joules that domiciliary treatment combined with a short term of hospital treatment has already got scores back to work in 6–9 months.

VARIOUS EXPERIENCE

But the service is uneven. These patients may be contrasted with the wife and a friend of another speaker at the meeting, Mr. L. C. JINKS. His wife, diagnosed as an early case 6 months ago, has been told that she has another 3 months to wait for a sanatorium bed. The friend was referred for major surgical treatment to a thoracic unit, and has already been waiting 12 months. Other speakers mentioned similar failures. Dr. A. ELLIOT described himself as coming from a backward area. He sent a barmaid with hæmoptysis to the chest clinic, and after she had been obliged to queue for some time in the rain, she was radiographed and later told she was not an active case; 18 months afterwards her disease was found to be active, and she was told to go home to bed for 9 months. She lived in lodgings, and could not go to bed; and there were children in the house. Moreover, the tuberculosis officer said he did not believe in domiciliary treatment. None of the voluntary bodies approached by Dr. Elliot could help, and finally, as he said, he "kicked up a row with the tuberculosis officer" and she got a bed in a week. Dr. DAVID KERR, on the other hand, reported that they have a good tuberculosis clinic in his area, but that it is used for maternity and child welfare the day after the clinic is held. He too had stories of people waiting for a bed and deteriorating, perhaps beyond hope. Other speakers mentioned poorly equipped clinics lacking X-ray apparatus. Dr. JOULES said that the Ministry of Health has a large quantity of X-ray apparatus available, which can be had on application. Dr. H. GRUNWALD urged the value of mobile clinics with X-ray equipment.

Dr. H. L. TRENCHARD spoke of the difficulty of providing domiciliary treatment for people who have no homes. He has been asked to let them stay on in hospital and go out to work. Hostels and night sanatoria are needed, he said; and the local authorities have powers to provide them, but little has yet been done. Patients in the Metropolitan area are particularly badly off: before the National Health Service began the London authorities could hire beds in sanatoria outside their area, but these beds are now controlled by the regional hospital boards, who naturally think first of their own patients. Mr. J. ROBERTSON suggested that Glasgow is the blackest spot in this black problem, and Dr. S. LEFF gave some figures bearing this out. Three people die of tuberculosis in Glasgow for every one in Aberdeen; and three die in the Gorbals and Govan districts of Glasgow for every one in Cathcart and Langside. He noted how closely the high mortality-rate is associated with the shocking housing conditions in that city, where 30,000 are homeless and another 30,000 living in overcrowded homes.

DIFFICULTIES

The association of bad housing with tuberculosis was emphasised again and again throughout the meeting. Indeed, Dr. C. K. CULLEN felt that domiciliary treatment is often out of the question for this very reason. How can a housewife rest at home in bed? There may be no room which can be given up to her without disorganising the whole home, and it may be impossible to board out the children, or they may write unhappy letters asking to come home. He considers we are wasting money on tuberculosis because we are using half measures: we would save money in the long run by doubling what we spend now. He urged those present to collect statistics in their own areas, to call conferences under the ægis of trade councils, and to send resolutions to every interested party they could think of, not forgetting the Minister of Health.

Miss L. J. GROUT mentioned the difficulty of getting home helps for the tuberculous; and she described the increasing poverty into which the family falls when the earning member is at home with a long illness. In the past, treatment allowances could be officially supplemented; but under the National Health Service the actual sums received are sometimes lower than those which were available before the Act was passed. The result is that after some months the family is apt to be going short of food—just the opposite of what is needed if they are to resist infection.

Mr. C. M. HAWKIN, a member of a hospital management committee, and twenty years a mental nurse, spoke of the great danger of infection spreading among mental-hospital patients. He wished to see tuberculosis tackled "with the ferocity of D-day."

Miss ELEANOR BANHAM, an ex-patient, paid great tribute to the sanatoria and nurses, and to those who had ensured that she should have extra milk. Tuberculosis, she said, has been neglected by the public, the Government, and the trade unions—the fault is not in the service itself. Another patient, Mr. C. BENSTED, came from Papworth, and spoke enthusiastically of the importance of reablement, and of training the patient for a proper trade.

ACTION

Many ways of dealing with this social evil were mooted. Mr. JACOBS was clear that the trade-union movement must try to get to work on it. "If all the Socialist doctors in the House asked questions about it all the time," he said, "all they would get would be answers." He believes that nearly 90% of those who refuse examination by mass radiography do so because the finding of a lesion means poverty for their family. Mr. J. F. RADLEY wanted to see a trade-union advisory council on tuberculosis set up, and [illegible]tion-wide campaign [illegible] against the disease. A long resolu[illegible] on the Government to reorganise general-hospital beds so that early cases can be treated in general hospitals;

to provide night sanatoria and hostels for the infectious; to modernise hospitals and chest clinics and to build new ones; to increase domestic staff to relieve the nurses, and to raise the nurses' pay and improve their conditions of service; to ensure full pay to the infected health worker until reablement is complete; to step up the housing programme; and to give larger allowances to the patient and his family.

Dr. Leff, in summing up, announced that it had been decided to send a deputation from the association to the Ministry, and that three members of the organisations present were to be invited to join; and that a standing committee of the association was to be set up on tuberculosis, to which the organisations present were also invited to send representatives.

Parliament

The Medical Bill

In the House of Lords on April 18 Viscount **Addison**, Lord Privy Seal, moved the second reading of this Medical Bill. It was, he said, an entirely non-party measure and its introduction was welcomed by the General Medical Council. Its main purposes were to improve the standards of medical education, to secure better provision for instruction in the care of patients before a doctor was admitted to full registration, and to deal with the powers and status of the General Medical Council and others in questions affecting discipline.

In all professions, he continued, people really began to learn after they had nominally qualified, and this was abundantly true of those who had the care of human beings in real or imaginary sickness. It was therefore proposed that after qualification a doctor should be required to have not less than a year's practical experience of the care of patients under supervision in a hospital or other approved institution. He was assured that there were more vacancies in house-appointments in England and Wales than there were people qualifying each year. It would be for the General Medical Council to consider what was meant by the term "an approved institution." As it might not be practicable to bring this provision into force everywhere at any one time the G.M.C. would fix the date when it should come into operation.

The Bill also provided that the G.M.C. should be able to visit and inspect medical schools and examine their standards of training. Lord Addison felt, however, that there ought not to be too many bodies with power to inspect. Quite properly the universities and the University Grants Committee had the power, and the aim would be that this new power of inspection should be coördinated with the exercise of the same powers by these other bodies.

It had been represented for many years past that the constitution of the G.M.C. might be improved, and under this Bill the number of members of the council would be increased from 39 to 45. There would be a specially appointed disciplinary committee which, apart from the chairman, would have only 19 members, of whom substantially a third would be medical men who had been elected by their fellows. A medical man struck off the register would in future have an opportunity to appeal to the Judicial Committee of the Privy Council.

The fee for interim provisional registration would remain at 5 guineas as at present, but when the final interim period was finished and a man or woman was added to the register, the fee would be increased to 11 guineas. The statutory description of the body, instead of being the General Council of Medical Education and Registration of the United Kingdom, would in future be simply the General Medical Council—the title under which it had been generally known for many years past.

Lord **Horder** admitted that he had been a severe and unrepentant critic of the Government during the last two or three years, but he supported this Bill. He believed that the first five clauses, if properly administered, would add considerably to the efficiency of doctoring and general practice in Britain. The Bill did not improve the conditions of doctoring, but it gave the doctor the best chance of being efficient. Immediately after qualification, and synchronously with registration, the young doctor went out into practice ill fitted in the sense of responsibility and judgment (which was born only of experience) and the ability to declare the inherent principle which was in him. If properly administered the present Bill could do much to remedy this. But several points called for careful consideration. Was it clear that this additional year was to be added to the present 5–6 years of the ordinary curriculum? The position should be safeguarded, so that the present curriculum was not modified to make this desirable twelve months part of the 5-year or 6-year period. Again, what was to be the status of the qualified but only provisionally registered doctor? Lord Horder suggested that the provisional registration should entitle the newly qualified doctor to full responsibility and privileges within the terms of his appointment, such as were accorded to registered medical practitioners in general. For example, would he be legally entitled to prescribe dangerous drugs? Might he sign death certificates or certify as to insanity? Should his remuneration be the same as the present rates for house-appointments? Lord Horder did not feel certain that there were enough suitable hospital appointments available for these provisionally registered doctors. He thought that any approved hospital should be able to provide a minimum of 20 beds or an equivalent number of outpatients. If there were not sufficient of these institutional posts he suggested that some of these people should be accredited to recognised approved groups of practitioners. This might be an incentive to get on with the health centres so as to provide some venue in which these young people could work. The idolatry of the hospital had gone rather far. These young men and women were ultimately going to be faced with domiciliary practice. The object was to make them more efficient doctors, not to feed their already avid desire to leave the ranks of general practice and become specialists.

In the wording of the Bill, Lord Horder further thought the medical and surgical spheres could be so expanded as to include specialties, such as diseases of children, diseases of the eye, diseases of the skin, and obstetric practice. Special hospitals where these important subjects were taught would be an admirable field in which to place a number of the provisionally registered men and women.

Turning to the second part of the Bill, Lord Horder pleaded for fuller direct representation. If you wanted to keep order in a house you should give some power to the master of the house. If the penal cases committee, which was a sifting committee, was to continue he hoped it would have a different personnel from the disciplinary committee who had the final say in matters brought before them. He understood that, though not bound to do so under the Medical Act of 1858, the G.M.C did arrange for "due inquiry" when a doctor had been convicted of felony or misdemeanour. As he read the present Bill it would be possible for the council to erase a doctor's name in these circumstances without a formal inquiry. He was informed by the defence bodies of the medical profession, who handled 90% of the cases on the doctors' behalf, that they considered it would be undesirable that there should be no formal inquiry, or that the habit of making an inquiry should be dropped. They strongly contended that section 20 should be amended to provide for due inquiry to take place in all cases.

Lord **Amulree** believed that if medical students were encouraged to spend part of the year with an approved panel of general practitioners it would make many of them more willing to go into general practice. Such a scheme would also improve the status of the general practitioner.

Lord **Webb-Johnson** regretted that the first two clauses of the Bill had been drawn so rigidly. A period of 12 months might prove not to be practicable. If the G.M.C. were not so rigidly bound the reforms which they all heartily desired could be introduced at an earlier date. In the case of a practitioner or qualified man in the Commonwealth or from a foreign country, the G.M.C. were empowered to accept that he had "otherwise acquired such experience." The same provision

are the measures taken in the Central Middlesex Hospital, of which he is medical superintendent; and he hopes to be able to show that there is no greater incidence of tuberculosis among the nurses in his general wards than among girls in the general population. He warns prospective nurses and their parents that they will be expected to nurse tuberculosis, and has never found this to have a detrimental effect on recruitment. Sanatoria, however, are hard put to it to get nurses. He mentioned a tuberculosis hospital of 760 beds in the Metropolitan area: half the beds are closed, and to staff the remainder the hospital has only a third the number of trained nurses and a seventh the number of students, per 100 beds, to be found in any major general hospital. These general hospitals, so lavishly staffed in comparison, should not have the right to second to sanatoria patients whom they will not nurse themselves.

Dr. C. H. C. Toussaint, chest physician to the Central Middlesex Hospital, noted that the incidence of tuberculosis among nurses there is far lower than that in any hospital investigated by the Prophit survey. He described three typical cases to show the advantages of combined hospital and domiciliary treatment: all were early cases in young people, all were admitted the day after he first saw them, all were sputum-negative within 2–3 months, and all went home for continued bed rest after a few weeks in hospital. Two are back in full work, less than a year after the onset, and the third—a boy of 15—was admitted with pneumonic tuberculosis last December and sent home sputum-negative and with a rising weight two months later. These case-histories reinforced a remark of Dr. Joules that domiciliary treatment combined with a short term of hospital treatment has already got scores back to work in 6–9 months.

VARIOUS EXPERIENCE

But the service is uneven. These patients may be contrasted with the wife and a friend of another speaker at the meeting, Mr. L. C. Jinks. His wife, diagnosed as an early case 6 months ago, has been told that she has another 3 months to wait for a sanatorium bed. The friend was referred for major surgical treatment to a thoracic unit, and has already been waiting 12 months. Other speakers mentioned similar failures. Dr. A. Elliot described himself as coming from a backward area. He sent a barmaid with hæmoptysis to the chest clinic, and after she had been obliged to queue for some time in the rain, she was radiographed and later told she was not an active case; 18 months afterwards her disease was found to be active, and she was told to go home to bed for 9 months. She lived in lodgings, and could not go to bed; and there were children in the house. Moreover, the tuberculosis officer said he did not believe in domiciliary treatment. None of the voluntary bodies approached by Dr. Elliot could help, and finally, as he said, he "kicked up a row with the tuberculosis officer" and she got a bed in a week. Dr. David Kerr, on the other hand, reported that they have a good tuberculosis clinic in his area, but that it is used for maternity and child welfare the day after the clinic is held. He too had stories of people waiting for a bed and deteriorating, perhaps beyond hope. Other speakers mentioned poorly equipped clinics lacking X-ray apparatus. Dr. Joules said that the Ministry of Health has a large quantity of X-ray apparatus available, which can be had on application. Dr. H. Grunwald urged the value of mobile clinics with X-ray equipment.

Dr. H. L. Trenchard spoke of the difficulty of providing domiciliary treatment for people who have no homes. He has been asked to let them stay on in hospital and go out to work. Hostels and night sanatoria are needed, he said; and the local authorities have powers to provide them, but little has yet been done. Patients in the Metropolitan area are particularly badly off: before the National Health Service began the London authorities could hire beds in sanatoria outside their area, but these beds are now controlled by the regional hospital boards, who naturally think first of their own patients. Mr. J. Robertson suggested that Glasgow is the blackest spot in this black problem, and Dr. S. Leff gave some figures bearing this out. Three people die of tuberculosis in Glasgow for every one in Aberdeen; and three die in the Gorbals and Govan districts of Glasgow for every one in Cathcart and Langside. He noted how closely the high mortality-rate is associated with the shocking housing conditions in that city, where 30,000 are homeless and another 30,000 living in overcrowded homes.

DIFFICULTIES

The association of bad housing with tuberculosis was emphasised again and again throughout the meeting. Indeed, Dr. C. K. Cullen felt that domiciliary treatment is often out of the question for this very reason. How can a housewife rest at home in bed? There may be no room which can be given up to her without disorganising the whole home, and it may be impossible to board out the children, or they may write unhappy letters asking to come home. He considers we are wasting money on tuberculosis because we are using half measures: we would save money in the long run by doubling what we spend now. He urged those present to collect statistics in their own areas, to call conferences under the ægis of trade councils, and to send resolutions to every interested party they could think of, not forgetting the Minister of Health.

Miss L. J. Grout mentioned the difficulty of getting home helps for the tuberculous; and she described the increasing poverty into which the family falls when the earning member is at home with a long illness. In the past, treatment allowances could be officially supplemented; but under the National Health Service the actual sums received are sometimes lower than those which were available before the Act was passed. The result is that after some months the family is apt to be going short of food—just the opposite of what is needed if they are to resist infection.

Mr. C. M. Hawkin, a member of a hospital management committee, and twenty years a mental nurse, spoke of the great danger of infection spreading among mental-hospital patients. He wished to see tuberculosis tackled "with the ferocity of D-day."

Miss Eleanor Banham, an ex-patient, paid great tribute to the sanatoria and nurses, and to those who had ensured that she should have extra milk. Tuberculosis, she said, has been neglected by the public, the Government, and the trade unions—the fault is not in the service itself. Another patient, Mr. C. Bensted, came from Papworth, and spoke enthusiastically of the importance of reablement, and of training the patient for a proper trade.

ACTION

Many ways of dealing with this social evil were mooted. Mr. Jacobs was clear that the trade-union movement must try to get to work on it. "If all the Socialist doctors in the House asked questions about it all the time," he said, "all they would get would be answers." He believes that nearly 90% of those who refuse examination by mass radiography do so because the finding of a lesion means poverty for their family. Mr. J. F. Radley wanted to see a trade-union advisory council on tuberculosis set up, and a nation-wide campaign against the disease. A long resolution was passed, calling on the Government to reorganise general-hospital beds so that early cases can be treated in general hospitals;

to provide night sanatoria and hostels for the infectious: to modernise hospitals and chest clinics and to build new ones; to increase domestic staff to relieve the nurses, and to raise the nurses' pay and improve their conditions of service; to ensure full pay to the infected health worker until reablement is complete: to step up the housing programme: and to give larger allowances to the patient and his family.

Dr. LEFF, in summing up, announced that it had been decided to send a deputation from the association to the Ministry, and that three members of the organisations present were to be invited to join; and that a standing committee of the association was to be set up on tuberculosis, to which the organisations present were also invited to send representatives.

Parliament

The Medical Bill

IN the House of Lords on April 18 Viscount ADDISON, Lord Privy Seal, moved the second reading of this Medical Bill. It was, he said, an entirely non-party measure and its introduction was welcomed by the General Medical Council. Its main purposes were to improve the standards of medical education, to secure better provision for instruction in the care of patients before a doctor was admitted to full registration, and to deal with the powers and status of the General Medical Council and others in questions affecting discipline.

In all professions, he continued, people really began to learn after they had nominally qualified, and this was abundantly true of those who had the care of human beings in real or imaginary sickness. It was therefore proposed that after qualification a doctor should be required to have not less than a year's practical experience of the care of patients under supervision in a hospital or other approved institution. He was assured that there were more vacancies in house-appointments in England and Wales than there were people qualifying each year. It would be for the General Medical Council to consider what was meant by the term "an approved institution." As it might not be practicable to bring this provision into force everywhere at any one time the G.M.C. would fix the date when it should come into operation.

The Bill also provided that the G.M.C. should be able to visit and inspect medical schools and examine their standards of training. Lord Addison felt, however, that there ought not to be too many bodies with power to inspect. Quite properly the universities and the University Grants Committee had the power, and the aim would be that this new power of inspection should be coördinated with the exercise of the same powers by these other bodies.

It had been represented for many years past that the constitution of the G.M.C. might be improved, and under this Bill the number of members of the council would be increased from 39 to 45. There would be a specially appointed disciplinary committee which, apart from the chairman, would have only 19 members, of whom substantially a third would be medical men who had been elected by their fellows. A medical man struck off the register would in future have an opportunity to appeal to the Judicial Committee of the Privy Council.

The fee for interim provisional registration would remain at 5 guineas as at present, but when the final interim period was finished and a man or woman was added to the register, the fee would be increased to 11 guineas. The statutory description of the body, instead of being the General Council of Medical Education and Registration of the United Kingdom, would in future be simply the General Medical Council—the title under which it had been generally known for many years past.

Lord HORDER admitted that he had been a severe and unrepentant critic of the Government during the last two or three years, but he supported this Bill. He believed that the first five clauses, if properly administered, would add considerably to the efficiency of doctoring and general practice in Britain. The Bill did not improve the conditions of doctoring, but it gave the doctor the best chance of being efficient. Immediately after qualification, and synchronously with registration, the young doctor went out into practice ill fitted in the sense of responsibility and judgment (which was born only of experience) and the ability to declare the inherent principle which was in him. If properly administered the present Bill could do much to remedy this. But several points called for careful consideration. Was it clear that this additional year was to be added to the present 5–6 years of the ordinary curriculum? The position should be safeguarded, so that the present curriculum was not modified to make this desirable twelve months part of the 5-year or 6-year period. Again, what was to be the status of the qualified but only provisionally registered doctor? Lord Horder suggested that the provisional registration should entitle the newly qualified doctor to full responsibility and privileges within the terms of his appointment, such as were accorded to registered medical practitioners in general. For example, would he be legally entitled to prescribe dangerous drugs? Might he sign death certificates or certify as to insanity? Should his remuneration be the same as the present rates for house-appointments? Lord Horder did not feel certain that there were enough suitable hospital appointments available for these provisionally registered doctors. He thought that any approved hospital should be able to provide a minimum of 20 beds or an equivalent number of outpatients. If there were not sufficient of these institutional posts he suggested that some of these people should be accredited to recognised approved groups of practitioners. This might be an incentive to get on with the health centres so as to provide some venue in which these young people could work. The idolatry of the hospital had gone rather far. These young men and women were ultimately going to be faced with domiciliary practice. The object was to make them more efficient doctors, not to feed their already avid desire to leave the ranks of general practice and become specialists.

In the wording of the Bill, Lord Horder further thought the medical and surgical spheres could be so expanded as to include specialties, such as diseases of children, diseases of the eye, diseases of the skin, and obstetric practice. Special hospitals where these important subjects were taught would be an admirable field in which to place a number of the provisionally registered men and women.

Turning to the second part of the Bill, Lord Horder pleaded for fuller direct representation. If you wanted to keep order in a house you should give some power to the master of the house. If the penal cases committee, which was a sifting committee, was to continue he hoped it would have a different personnel from the disciplinary committee who had the final say in matters brought before them. He understood that, though not bound to do so under the Medical Act of 1858, the G.M.C did arrange for "due inquiry" when a doctor had been convicted of felony or misdemeanour. As he read the present Bill it would be possible for the council to erase a doctor's name in these circumstances without a formal inquiry. He was informed by the defence bodies of the medical profession, who handled 90% of the cases on the doctors' behalf, that they considered it would be undesirable that there should be no formal inquiry, or that the habit of making an inquiry should be dropped. They strongly contended that section 20 should be amended to provide for due inquiry to take place in all cases.

Lord AMULREE believed that if medical students were encouraged to spend part of the year with an approved panel of general practitioners it would make many of them more willing to go into general practice. Such a scheme would also improve the status of the general practitioner.

Lord WEBB-JOHNSON regretted that the first two clauses of the Bill had been drawn so rigidly. A period of 12 months might prove not to be practicable. If the G.M.C. were not so rigidly bound the reforms which they all heartily desired could be introduced at an earlier date. In the case of a practitioner or qualified man in the Commonwealth or from a foreign country, the G.M.C. were empowered to accept that he had "otherwise acquired such experience." The same provision

are the measures taken in the Central Middlesex Hospital, of which he is medical superintendent; and he hopes to be able to show that there is no greater incidence of tuberculosis among the nurses in his general wards than among girls in the general population. He warns prospective nurses and their parents that they will be expected to nurse tuberculosis, and has never found this to have a detrimental effect on recruitment. Sanatoria, however, are hard put to it to get nurses. He mentioned a tuberculosis hospital of 760 beds in the Metropolitan area: half the beds are closed, and to staff the remainder the hospital has only a third the number of trained nurses and a seventh the number of students, per 100 beds, to be found in any major general hospital. These general hospitals, so lavishly staffed in comparison, should not have the right to second to sanatoria patients whom they will not nurse themselves.

Dr. C. H. C. **TOUSSAINT**, chest physician to the Central Middlesex Hospital, noted that the incidence of tuberculosis among nurses there is far lower than that in any hospital investigated by the Prophit survey. He described three typical cases to show the advantages of combined hospital and domiciliary treatment: all were early cases in young people, all were admitted the day after he first saw them, all were sputum-negative within 2–3 months, and all went home for continued bed rest after a few weeks in hospital. Two are back in full work, less than a year after the onset, and the third—a boy of 15—was admitted with pneumonic tuberculosis last December and sent home sputum-negative and with a rising weight two months later. These case-histories reinforced a remark of Dr. Joules that domiciliary treatment combined with a short term of hospital treatment has already got scores back to work in 6–9 months.

VARIOUS EXPERIENCE

But the service is uneven. These patients may be contrasted with the wife and a friend of another speaker at the meeting, Mr. L. C. **JINKS**. His wife, diagnosed as an early case 6 months ago, has been told that she has another 3 months to wait for a sanatorium bed. The friend was referred for major surgical treatment to a thoracic unit, and has already been waiting 12 months. Other speakers mentioned similar failures. Dr. A. **ELLIOT** described himself as coming from a backward area. He sent a barmaid with hæmoptysis to the chest clinic, and after she had been obliged to queue for some time in the rain, she was radiographed and later told she was not an active case; 18 months afterwards her disease was found to be active, and she was told to go home to bed for 9 months. She lived in lodgings, and could not go to bed; and there were children in the house. Moreover, the tuberculosis officer said he did not believe in domiciliary treatment. None of the voluntary bodies approached by Dr. Elliot could help, and finally, as he said, he "kicked up a row with the tuberculosis officer" and she got a bed in a week. Dr. DAVID **KERR**, on the other hand, reported that they have a good tuberculosis clinic in his area, but that it is used for maternity and child welfare the day after the clinic is held. He too had stories of people waiting for a bed and deteriorating, perhaps beyond hope. Other speakers mentioned poorly equipped clinics lacking X-ray apparatus. Dr. **JOULES** said that the Ministry of Health has a large quantity of X-ray apparatus available, which can be had on application. Dr. H. **GRUNWALD** urged the value of mobile clinics with X-ray equipment.

Dr. H. L. **TRENCHARD** spoke of the difficulty of providing domiciliary treatment for people who have no homes. He has been asked to let them stay on in hospital and go out to work. Hostels and night sanatoria are needed, he said; and the local authorities have powers to provide them, but little has yet been done. Patients in the Metropolitan area are particularly badly off: before the National Health Service began the London authorities could hire beds in sanatoria outside their area, but these beds are now controlled by the regional hospital boards, who naturally think first of their own patients. Mr. J. **ROBERTSON** suggested that Glasgow is the blackest spot in this black problem, and Dr. S. **LEFF** gave some figures bearing this out. Three people die of tuberculosis in Glasgow for every one in Aberdeen; and three die in the Gorbals and Govan districts of Glasgow for every one in Cathcart and Langside. He noted how closely the high mortality-rate is associated with the shocking housing conditions in that city, where 30,000 are homeless and another 30,000 living in overcrowded homes.

DIFFICULTIES

The association of bad housing with tuberculosis was emphasised again and again throughout the meeting. Indeed, Dr. C. K. **CULLEN** felt that domiciliary treatment is often out of the question for this very reason. How can a housewife rest at home in bed? There may be no room which can be given up to her without disorganising the whole home, and it may be impossible to board out the children, or they may write unhappy letters asking to come home. He considers we are wasting money on tuberculosis because we are using half measures: we would save money in the long run by doubling what we spend now. He urged those present to collect statistics in their own areas, to call conferences under the ægis of trade councils, and to send resolutions to every interested party they could think of, not forgetting the Minister of Health.

Miss L. J. **GROUT** mentioned the difficulty of getting home helps for the tuberculous; and she described the increasing poverty into which the family falls when the earning member is at home with a long illness. In the past, treatment allowances could be officially supplemented; but under the National Health Service the actual sums received are sometimes lower than those which were available before the Act was passed. The result is that after some months the family is apt to be going short of food—just the opposite of what is needed if they are to resist infection.

Mr. C. M. **HAWKIN**, a member of a hospital management committee, and twenty years a mental nurse, spoke of the great danger of infection spreading among mental-hospital patients. He wished to see tuberculosis tackled "with the ferocity of D-day."

Miss **ELEANOR BANHAM**, an ex-patient, paid great tribute to the sanatoria and nurses, and to those who had ensured that she should have extra milk. Tuberculosis, she said, has been neglected by the public, the Government, and the trade unions—the fault is not in the service itself. Another patient, Mr. C. **BENSTED**, came from Papworth, and spoke enthusiastically of the importance of reablement, and of training the patient for a proper trade.

ACTION

Many ways of dealing with this social evil were mooted. Mr. **JACOBS** was clear that the trade-union movement must try to get to work on it. "If all the Socialist doctors in the House asked questions about it all the time," he said, "all they would get would be answers." He believes that nearly 90% of those who refuse examination by mass radiography do so because the finding of a lesion means poverty for their family. Mr. J. F. **RADLEY** wanted to see a trade-union advisory council on tuberculosis set up, and a nation-wide campaign against the disease. A long resolution was passed, calling on the Government to reorganise general-hospital beds so that early cases can be treated in general hospitals;

4 of the nurses and the laundry maid died. Compulsory vaccination would be difficult to justify in view of the fact that Parliament had abolished universal compulsion. It would also be somewhat of a deterrent to staff recruitment at fever hospitals, where such difficulties were perhaps more evident than in any other class of hospital in the country. The original Glasgow case was admitted to hospital for pneumonia which might well have been dealt with in a general hospital, while 1 other case, that from Hamilton, was, in fact, admitted on a mistaken diagnosis to a general hospital. It would be somewhat illogical to make vaccination compulsory for fever-hospital staffs but not for general-hospital and public-health staffs, including sanitary inspectors.

Hospital Endowments Fund

In the House of Commons on April 19 Sir John Mellor moved that the National Health Service (Hospital Endowments Fund—Discharge of Liabilities) Regulations, 1950, be annulled. He said that the regulations did not define the extent of the liabilities which the Minister might discharge out of the fund. The Minister was asking the House to give him a blank cheque on the fund. The House should be told the present value of the fund and the amount of the liabilities taken over by the Minister in connection with the voluntary hospitals.

Mr. Arthur Blenkinsop, parliamentary secretary to the Ministry of Health, said it was unfortunate that it was not possible to produce accounts before the regulations were put forward. The first of the accounts, however, would be presented shortly. Even now the transfer of assets had not been completed. The Ministry were still dealing with many thousands of separate endowments and it had proved a very complex and detailed matter. They were now in a position to estimate pretty accurately the total liabilities to be met. The total assets would certainly be not less than £20 million. The gross value of the fund should be approximately £30 million. There would be approximately £11 million to meet liabilities, which included £6 million for bank overdrafts. The motion was negatived.

Bulk Prescribing and Advertising

In the House of Commons on April 20 Mr. Hugh Linstead moved that the regulations dated Dec. 16, 1949, entitled the National Health Service (General Medical and Pharmaceutical Services) Amendment (No. 2) Regulations, 1949 (S.I. 1949, No. 2341) be annulled. He said that regulation 11 permitted in an institution a doctor who was responsible for the medical care of the inmates to write prescriptions for stocks of drugs and medicines instead of writing prescriptions for individual patients. A provision whereby bulk medicines were prescribed to institutions to be kept in store until somebody there required them was a complete departure from the principle of a medical service. He believed the intention had been to meet a complaint from boarding-schools where it had been customary to keep stocks of medicine. But why choose one type of institution for preferential treatment? Why should factory proprietors be expected to pay for the medicines in their sick bays while the governors of a boarding-school were given free medicines to stock their medicine cupboards?

Another point, Mr. Linstead continued, was that the Minister had permitted competitive advertising among chemists against the advice of the Pharmaceutical Society, who had laid down that advertisements should not refer to dispensing services.

Mr. Blenkinsop agreed that in general the practitioner should prescribe individually for each patient and that had been the principle on which the service had been founded; but in practice it had been found that there were exceptional cases where its application would be wasteful both of the time of the doctor and the patient, and of medicine bottles and medicines. For instance, at an institution where there might be some mild infection, the doctor under the existing regulations had to make out a separate prescription form for each patient. But it was appreciated that problems might arise, and the matter would be carefully watched. Schools and residential institutions were in a different category from factories because their doctor was the regular doctor who provided care for patients. In a factory, first-aid or emergency treatment was offered and the worker was still on the list of his own doctor.

Turning to Mr. Linstead's second point, he said advertising could be undertaken solely in chemists' windows and within the approved wording. It was not quite fair to say that the profession were unanimous about this matter: there were three points of view. Some chemists suggested that the present position should be retained. Others urged that there should be completely free opportunity to advertise. A further group suggested a restricted form of advertising should be allowed in approved wording not only in shop windows, but also in the press and in other ways. The Ministry felt that it was fair, in view of the representations which had been made to them, and the differing points of view, to adopt the middle course. But these changes would be kept under review, and if there appeared to be any abuse the Ministry would be willing to make such amendment of the regulations as might be necessary. *The motion for annulment was withdrawn.*

QUESTION TIME

Cost of N.H.S. Drugs and Appliances

Replying to a question, Mr. Aneurin Bevan stated that the total amount paid to chemists in England and Wales for drugs and appliances under the National Health Service up to Feb. 28, 1950, was just over £41 million. A running 1% sample suggested the following approximate percentage cost for 1949:

Appliances	*Proprietaries*	*Other preparations*
10%	28–29%	61–62%

Reciprocal Benefits

In answer to a question, Dr. Edith Summerskill stated that the only reciprocal arrangement so far made with a foreign country for providing insurance benefits for British nationals in that country was with France. Negotiations were proceeding with a number of other countries.

Trial Release of Mental Defectives

Mr. N. N. Dodds asked the Minister of Health if arrangements could be made for appeals to an independent body of experts, from decisions of local hospital committees refusing applications for a trial release from hospitals or homes of mental defectives.—Mr. Bevan *replied*: *I am not satisfied that there is a sufficient case for modifying the present arrangements.*

Trypanosomiasis in West Africa

Mr. Thomas Reid asked the Secretary of State for the Colonies, in view of the wide prevalence of trypanosomiasis in West Africa, what reports he had received of the treatment of this disease by the use of 'Antrycide.'—Mr. T. F. Cook *replied*: *The department's tsetse fly and trypanosomiasis committee has recently been considering reports from many parts of Africa, including West Africa, concerning experiments in the use of antrycide in cases of animal trypanosomiasis. These reports tend to confirm the curative merits of the drug, but, owing to the danger of toxicity and drug resistance, expert advisers are agreed that further experimental work is required into its prophylactic qualities. This work will be pursued.*

Salaries of Local Authority Dentists

Mr. E. H. Keeling asked the Minister of Health how soon Whitley machinery would be set up to negotiate new salaries for dentists in the service of local authorities—Mr. Bevan *replied*: *Progress in setting up a Dental Whitley Council now depends entirely on the representatives of the dental profession.*

Hospital Staffs

Mr. K. W. M. Pickthorn asked the Minister of Health what were the numbers and the costs of the clerical and administrative staffs of hospitals for each of the last four years.—Mr. Bevan *replied*: *Figures are available for only the last two years. On Dec. 31, 1948, when staff was still being built up and much of the administrative work was being done by local authorities on an agency basis, the total clerical and administrative staff of hospitals was 20,933. On Dec. 31, 1949, when the agency* [illegible] *een superseded, the figure was 25,654.* [illegible] *res of cost are not available, but the c* [illegible] *in the financial* might well be applied to our own countrymen. He thought that the disciplinary committee was too large and he supported Lord Horder's view that there should be some sifting committee independent of the tribunal. He was considerably disturbed that the decision of this tribunal could be made by the casting vote of the chairman. He thought that there might be some power to give some other sentence than erasure from the register. He also supported the suggestion that even if there was a report on conviction, or a report of something in divorce proceedings which was regarded as "infamous conduct," it should be the duty of the disciplinary committee to hold their own inquiry. His only anxiety with regard to the appeal was lest the cost of appeal to the judicial committee of the Privy Council should be prohibitive.

Finally, Lord Webb-Johnson urged that as this was a Medical Bill and not a General Medical Bill they should consider whether there was any important point outside the provisions already drafted which might be included. One point which had been brought to his notice was that while the curriculum was extended for a year, while the training was more exacting, and while the public were more dependent on scientific guidance in time of illness, the maximum penalty for a man masquerading as a qualified practitioner without any grounds for so doing was only £20.

Viscount JOWITT, the Lord Chancellor, frankly admitted that he, too, regarded a disciplinary committee of 19 as rather large; he would have preferred a committee of, say, 9 which was a quorum with its chairman. However, this point had been discussed with the G.M.C. and they were anxious that all interests should be represented. The matter could be considered in the committee stage. The advantage of an appeal to the Privy Council was that the appeal would be to a court which had upon it the most eminent judges from England, Scotland, and Northern Ireland. The proposal had given the medical profession complete satisfaction. The idea that an appeal to the Privy Council was necessarily expensive was wrong. He had no doubt they would be able to avoid undue expense falling on an appellant. In clause 19 it was proposed that where the name of a person had been erased from the register the committee might, if they thought fit, at any time direct the registrar to restore it. As the law stood wherever there had been a conviction the G.M.C. took that as a fact. They only considered whether that conviction was of such a grave character that it should involve a man being struck off the register. In the case of adultery they had to consider whether the circumstances made it an act of professional misconduct. He thought that was the right way to approach the matter, but it was a question which the Government would certainly consider in the committee stage if noble Lords so desired.

Lord HADEN-GUEST pointed out that many doctors already did six months' or a year's training after completing their normal studies, and he believed that there would be enough places to provide appointments for all who required them. Turning to Lord Horder's suggestion that health centres might be approved institutions, he said that a health centre was not primarily a building but a group of doctors working together as a team. Some were already being formed, and it seemed to him very desirable that young doctors should be apprenticed to such a group as an alternative to going into some institution.

Lord STAMP, in a maiden speech, pointed out that the medical schools of the University of London were already visited regularly by the senate of the university, and the University Grants Committee now also proposed to visit them every 5 years. The proposed visits by representatives of the G.M.C. would lead to an increased danger of overlapping and of inconvenience due to multiple inspections and reports. He hoped arrangements could be made for representatives of the interested bodies to visit the schools as a single body.

Lord SHEPHERD, replying to the debate, said the Government would certainly look into Lord Webb-Johnson's suggestion that clauses 1 and 2 were too rigidly drawn. But at the same time he pointed out that those clauses were in accord with the report of the Goodenough Committee. Moreover, the two clauses had since received the approval of the G.M.C. It was the intention of the Government that the interns should occupy house-posts and that the rate for the job should be paid. The appointed day for the disciplinary committee could come into operation almost forthwith, but a good many problems had to be solved in regard to the interns, and this provision would become compulsory only as and when circumstances permitted. Replying to Lord Horder's speech, Lord Shepherd said he could not answer specifically the question whether an intern would be able to issue death certificates or deal with drugs; but under sub-section (3) of clause 4 it was contemplated that an intern would be registered only in so far as certain functions could be performed and no further. He did not think they need fear that the hospitals and institutions secured for the purpose of intern training would be other than suitable and practical. The universities and other examining bodies could be trusted to make a proper choice.

Recruitment of R.A.M.C. Officers

In the debate on Army problems in the House of Lords on April 19, Lord WEBB-JOHNSON returned to the point he had made in the recent debate on defence [1] that the shortage of specialists in the R.A.M.C. was only likely to be overcome by the integration of the Army Service with the National Health Service and by secondment of officers from the N.H.S. to the Armed Forces. Unfortunately, since that proposal was put forward officially as a recommendation to the Minister of Defence, to the Secretaries of State, and to the Cabinet, many posts had been filled without any such obligations of secondment. The establishment of R.A.M.C. officers was 915, including long-term and short-term commissions, and the total deficiency was 342; the deficiency in the number of long-term officers was 10%; the deficiency on short-term commissions was 64%; and the over-all deficiency was 37%. These figures showed that the R.A.M.C. was in danger of running down beyond chance of recovery. The only remedy was improvement of terms and conditions of service. It was a comparatively easy matter to determine how remuneration in the civilian National Health Service and remuneration in the R.A.M.C. could be brought within reasonable comparison of each other.

Lord PAKENHAM, Minister of Civil Aviation, in his reply said that the matter raised by Lord Webb-Johnson was regarded by the Government as one of real urgency. It was past the stage of "being considered," and even past the further stage of "being examined." The consideration now being given to it was exactly the sort of consideration which Lord Webb-Johnson would expect, and Lord Pakenham promised him every opportunity for casting stones if nothing was done by the time their Lordships next came to debate it.

Vaccination of Fever Hospital Workers

In the House of Lords on April 19, Lord CLYDESMUIR asked whether, in view of the experience of the recent outbreak of smallpox, the Government would consider the advisability of making periodic vaccination compulsory for all those who worked in fever hospitals. Lord MORRISON, replying for the Government, said it was of course the general rule that the staffs of smallpox hospital units should be drawn entirely from persons protected by vaccination. While emphasising the desirability of vaccination for staffs employed at fever hospitals, or otherwise liable to come into contact with smallpox, the Minister of Health and the Secretary of State for Scotland did not feel justified at present in making vaccination a condition of service. Both Ministers were, however, reminding hospital and other authorities of the need to ensure that vaccination was offered to all persons on recruitment to such staffs and periodically to all persons so employed. In answer to a further question he added that out of the 21 smallpox cases in the recent West of Scotland outbreak, 9 were members of the staff of the fever hospital in which the original case was treated. The original case was undiagnosed when the man entered the hospital. Some of the 9 cases mentioned were not adequately protected by vaccination. They included 8 nurses and 1 laundry maid. Of these 9 people

In England Now

A Running Commentary by Peripatetic Correspondents

SOME occupations so stamp themselves on the features and bearing that they are easily identified by even the comparatively unobservant. Take jockeys, and indeed the whole class of "horsey" men, in whom constant equine contemplation and society produces a most characteristic facies. The Army man displays the fixed expression imposed by discipline, but it is not so easy to explain the distinctiveness of the sailor. Is it the sea, the breezes, the life, or the way of living? Thought we know has its effect in moulding the features; outstanding examples of this are the divine and the man of law. Is there a medical face? I have often glanced round a gathering of doctors and have decided that there is nothing whatever in their appearance to suggest the healing art in all or any of its manifold ramifications. One sees what might be dashing cavalry officers, film stars, prosperous brewers or butchers, country parsons, actors, farmers, policemen in plain clothes, and not a few like nothing on earth.

Does not our special education and training impose a single characteristic mark? A recent experience, stimulated by a paragraph in the journals, has thrown a little light on the problem. In the *New England Journal of Medicine* for March 23 (p. 430), quoted in *The Lancet* of April 15, one reads "The *internist* is recognisable by his preoccupied look, as a man wrestling with difficulties... considering every organ as a potential villain. The *surgeon* cuts more of a figure. . . . He exudes optimism and radiates confidence. The burden of accumulated uncertainty that weighs on the shoulders of the internist never bends the surgeon's erect structure." The Conjoint Finals were on and I took the opportunity to substitute for a haphazard collection of medical men the segregation in the examiners of physicians, surgeons, gynæcologists, and pathologists, and it seemed to me that the physicians did exhibit a sort of family resemblance distinct from their colleagues in the other specialties, whether or no this was attributable to the cause alleged.

I pondered as I left Queen Square, for other mundane explanations seemed at least feasible. As I turned into Southampton Row I ran into George, a middle-aged G.P. in practice in Bloomsbury. "Is there a typical medical face?" I asked him. "Of course there is," replied George with some bitterness, "it is unmistakable —a composite resulting from poverty-stricken senility and duodenal ulceration."

* * *

In Germany the buds are bursting, the birds singing, and the forsythia in full bloom; another month and the country roads will be bright with apple-blossom for mile after mile; only the mildest of winters separates us from last year's fruit crop, and the lengthening evenings and blue skies bring memories of last summer, and particularly of an old university town in the south, where the deep shadows of the narrow streets seemed all the deeper for the sun-drenched stucco of the overhanging gables. Here it was that I learnt what an *Ausflug* is. I had often read of *Ausflüge* in German lessons but had never before experienced one; there is no precise equivalent in English, but perhaps "expedition" is the nearest translation.

The houseman at the hospital where I was staying called at my room the evening before. "Tomorrow," he said, "I will take you for an *Ausflug*; your breakfast will come at quarter to seven, and I will come at quarter past." My breakfast (a fried egg, to my surprise) came at twenty to seven, and my guide at ten past. At a quarter to eight we were sitting on the hard slatted seats of a country train bound for Hechingen (onetime capital of the principality of Hohenzollern), complete with rucksack full of sausage sandwiches, bottles of mineral water, and a guidebook. The Hohenzollern castle, our objective, towers above the town, crowning a solitary hill which lies off the long limestone plateau known as the *Schwäbische Alb*, like a ship off shore. Burg Hohenzollern is an amazing sight; it caps a hill whose sides rise at first steeply, and then almost sheer, from the surrounding fields. An hour of steady climbing up small paths through dense pinewoods brought us to the summit. The castle is all that a castle should be: pointed turrets, battlements, and a succession of drawbridges leading to a courtyard on which the principal rooms open. There has been a castle here for a thousand years, but the present one was built by Kaiser Wilhelm I, grandfather of "the Kaiser" of world war I. We sat in the courtyard and ate a substantial meal from the rucksack before touring the castle—full-blooded Gothic revival on a Teutonically thorough scale.

That duty done we descended the other side of the hill, as steep as the side we had climbed up, and after scrambling up the northern slope of the *Schwäbische Alb* were rewarded with a superb view, marred by a slight mist, of the castle and the plain beyond, and, just visible to the west, the hills of the Black Forest. We were now on the summit of the Zellerhorn, a spur which juts out towards Burg Hohenzollern. After taking some photographs we settled down to a large lunch, which at last made some difference to the weight of the rucksack. I took this to be our midday meal, but I had misjudged the German appetite, for after another hour's walk across the rocky plateau we came to an inviting *Gasthaus* just over the brow. As we sat down, my companion asked cheerfully: "Well, what would you like for lunch? A pork chop, perhaps?" And pork chops it was, with an enormous dish of vegetables. It was as well that the rest of the way lay downhill. A winding chalky road brought us to a village called Onsmettingen, a railhead in the hills, whence we travelled over the Rhine-Danube watershed, back to Tübingen, and I had learnt the ingredients of a German *Ausflug*—an early start, a long walk with hills to climb, a rucksack, a guidebook, vast amounts of food, and a rendezvous with a country train to take you back when you're tired. How the princes of Hohenzollern, a tiny State in the south-west corner of the country, became German Emperors is another story; but I couldn't help thinking of the ill-fated Kaiser Friedrich III, now remembered as the "Ninety Day Emperor," who came to the throne in 1888 with a carcinoma of the larynx and a palliative tracheotomy.

* * *

Phyllis is a second-year student nurse at one of our famous teaching hospitals. "How do they look after your health?" I asked her; she was enthusiastic. "They take *great* care of us; there's always a doctor on duty to see anyone who likes to go to him between nine and half-past every morning." "Do you have to ask the sister?" "No, you just tell her you're going." She was looking thinner than I remembered, and had a dressing on her chin. At bedtime this came off and an over-ripe boil suddenly exuded about 2 c.cm. of pus. "I thought you said they looked after you. What were you doing on the ward with that thing?" I asked. "Oh well, that's my fault. If I'd gone to the doctor I expect he'd have sent me off." As she was doing a period of tuberculosis nursing, and was perhaps in contact with some surgical cases, I expected so too. "But why haven't you been to him?" "Oh well— we're always rather busy on the ward between nine and half-past."

How well these things look on paper.

* * *

When we moved into this house we took over some coal in the basement cellar which subsequently proved to be mostly dust. Since then a succession of purveyors of domestic help have adopted the view that lumps are intended for breaking up small, and an undue proportion of our "best" coal ration has arrived as powder; so our cellar has come to contain a great accumulation of dust. My Bank Holiday task was to search for buried lumps, attired in a boiler suit and gum-boots, with a theatre-mask over my nose and mouth. At the subsequent ablutions my nostrils were black, and a douche produced an astonishing nasopharyngeal deposit of coal-dust. It is true that the mask was very dirty, but the douche result seemed considerably worse.

This makes me wonder whether wearing a gauze mask can be really effective after all, or whether it is merely a fetish. Surely if coal-dust can pass in one direction, organisms can pass in the other?

year 1949–50 was estimated at £3½ million, and in the financial year 1950–51 at £4½ million.

Replying to a further question, Mr. BEVAN said it was quite impossible to make any estimates for the condition of things when the Ministry took over because voluntary hospitals had no uniform system of accounting which would throw up the various categories upon which the money was being spent.

Public Health

Scotland's Health Services

IN Scotland only one health centre—at Sighthill, a developing Edinburgh suburb—is to be constructed at the moment; and other ways are being sought to encourage coöperation among groups of general practitioners and their closer working with the public-health and hospital services. The first annual report of the Scottish Health Services Council [1] states that meanwhile the impact of the new service on the practitioner's work is being studied by the Standing Medical Advisory Committee; and "the Council feel it is their duty to put on record that in many quarters there is a conviction that certain features of the general practitioner services are operating to the disadvantage of the best types of general medical and dental practice."

The report of the Department of Health shows that the number of prescriptions dispensed under the National Health Service grew steadily from 706,000 in July, 1948, to 1,339,000 in December, 1948. In 1949 the January total of 1,567,000 was not surpassed until November, which, with a total of 1,581,000 was the peak month of the year. The numbers for the later months of 1949 are about one-quarter higher than for the same months of 1948; the total number of prescriptions for the calendar year 1949 was about 17 million. The cost per prescription also rose—from 40·8*d.* in September, 1948, to 46·4*d.* in April, 1949.

The number of new cases of respiratory tuberculosis provisionally notified in 1949 was 8427, compared with 8204 corrected notifications in the previous year and 7984 in 1947. However, in 1949 deaths were more than 10% fewer than in 1948. Notifications of non-respiratory tuberculosis declined to 1627 (provisional) in 1949, compared with 1842 and 2133 in 1948 and 1947. "There is no doubt that the efforts made in Scotland to eliminate tuberculosis from dairy herds and otherwise to improve the cleanliness and safety of the milk supply are largely responsible for these results."

During the late war there was undoubtedly a real increase in the incidence of respiratory tuberculosis, and this has continued into the post-war years;

> "but there is little doubt that the rising figures recently recorded are in part due to earlier diagnosis and improved methods of case finding. A stage has now been reached when 5 to 10 per cent. of all new cases coming to light are found through mass radiography. Many cases are now discovered in the relatively early stages when the disease is more susceptible to treatment, and it is probable that a great many of the cases of tuberculous disease of the lungs found by mass radiography would in the ordinary course of events have remained undiagnosed, but still infectious, for months or even years."

During the year the total number of beds for patients with respiratory tuberculosis was increased to 4895, from 4707 a year before. Nevertheless the number of patients awaiting admission at the end of the year was 2877, compared with 2572 at the end of 1948.

Smallpox in Glasgow

Speaking in Glasgow on April 18, the Lord Provost of the city criticised the time that elapsed between the date when the seaman through whom the recent outbreak of smallpox originated was admitted to a Glasgow hospital, and the date when official confirmation was received by the city corporation and medical officer. The seaman, he said, was admitted to hospital on March 10, and 18 days passed before the corporation was told of the disease. It was, he suggested, high time that steps were taken to see that never again would such a time elapse before Glasgow was informed of an impending epidemic.

In a letter to the Lord Provost, Mr. Hector McNeil, secretary of State for Scotland, remarks that it seemed that "you feared that the Western Regional Hospital Board had been guilty of delay in notifying to the Glasgow Public Health Department the original case of smallpox which led to the recent outbreak."

> "Now, it seems to me," Mr. McNeil continued, "that your statement suggests that there was some slackness in allowing this original case into the country without being isolated, and that further this function had been better done while it was the function of the local authority. I am sure there is some confusion here. Port health control is, of course, as I am sure you know, still in the hands of the local authorities and is not the job of the Regional Hospital Boards. However, here I do not want to be thought at all critical of the appropriate local authority."

Unhappily, continued Mr. McNeil, when the man who was the original contact landed in this country, he was apparently perfectly well.

> "I think you should know that on March 14th the hospital authorities told an officer of the Glasgow Public Health Department that the patient was thought to be suffering from chickenpox. This was, I am informed, the first day on which the patient had shown a rash, his admission to hospital on 10th March (arranged through the Public Health Department) having been on account of pneumonia. The information was given in the course of inquiry by the hospital authorities from the Public Health Department as to whether there was any record of illness on the ship in which he had come to the country; and I understand the Department took action to the extent of putting under daily observation the seamen's hostel from which he had been admitted. Further, a medical officer of the Department saw the patient in the hospital on March 17th. Suspected smallpox was first diagnosed on March 26th in contacts of the original case, and I am assured that the Public Health Department was informed by telephone that same day."

Sir Andrew Davidson, chief medical officer of the Department of Health for Scotland has sent to medical officers of health a letter thanking those concerned for their strenuous and successful efforts in controlling the outbreak.

Births and Deaths in England and Wales

The Registrar-General's weekly return for the week ended April 15 records the following rates for the quarter ended March 31 this year (rates for the corresponding quarter of 1949 in parentheses): birth-rate 16·7 (17·3) per 1000 population; stillbirth-rate 22·9 (23·1) per 1000 live and still births; death-rate 14·0 (14·9) per 1000 population; and infant-mortality rate 37 (40) per 1000 related live births.

Dysentery in England and Wales

The last week of the first quarter of the year (week ended April 1) produced 461 notifications of dysentery—the highest weekly figure recorded this year. The total number of notifications for the quarter were 3938, compared with 5163 in the corresponding period of the peak year 1945. There is therefore every indication of the present year becoming comparable to 1945 in dysentery incidence as judged by notifications.

The disease due to *Shigella sonnei* remains confined very largely to the North; the counties of Durham, Lancashire, Northumberland, and the West Riding have contributed 67·7% of all notifications in the first quarter. The county boroughs in these areas which had the highest figures were Sheffield (566), Leeds (365), Newcastle (183), Manchester (169), Bradford (127), and South Shields (87). At the other end of the scale the following places in the same areas recorded no notifications at all: Barrow-in-Furness, Blackpool, Bootle, Bury, Rochdale, Warrington, and Halifax; and the following registered only 1 case each: Darlington, Burnley, Oldham, Tynemouth, and York. County areas with figures next highest to those mentioned above were Gloucester, Stafford, and Glamorgan, which together were responsible for 9·7% of all notifications. In the remaining counties in the East and West the incidence was satisfactorily low.

[1] Report of the Department of Health for Scotland and of the Scottish Health Services Council, 1949. H.M. Stationery Office. Pp. 115. 3s.

unanimously found this treatment to be of no significant benefit in rheumatoid arthritis.

The total of cases treated amounts to 172. Of these some limited improvement was noted in 14 cases (subjective only in 11 and objective in 3). Many of us have had the opportunity of treating cases with adrenocorticotrophic hormone and of observing in the U.S.A. the therapeutic effects of 'Cortisone.' and we were convinced immediately of the very great value of these substances. In contrast, when cases are adequately studied under controlled and standardised conditions, treatment with deoxycortone and ascorbic acid produces no more improvement either subjectively or objectively than can be observed to follow other forms of injection treatment—e.g., procaine or even normal saline.

In view of the widespread publicity being given to the use of deoxycortone and ascorbic acid in the treatment of rheumatoid arthritis we have thought it desirable to report our failure to obtain any significant benefit and to record the unanimity with which we are agreed on this.

HÆMORRHAGE FROM PEPTIC ULCER

Sir,—There seems to be a world-wide interest just now in the surgical treatment of bleeding peptic ulcer, and recent papers have revealed a significant change in the accepted indications for operation.

In this department we have based our indications for operation on the investigations of Dr. Jorgen Pedersen in Meulengracht's department of the hospital. Pedersen[1] analysed some 850 cases of bleeding ulcer, covering a ten-year period up to May, 1948. He found that among the 530 patients under 40 years of age only 1 died. On the other hand, among the 317 over 40 there were 30 deaths, distributed as follows:

Type and time of hæmorrhage	*Cases*	*Deaths*
No visible bleeding	2	2 (100%)
Melæna	119	3 (2·5%)
Hæmatemesis *before admission*	128	4 (3·1%)
Hæmatemesis *in hospital*	68	21 (31%)
All cases in patients over 40 years	317	30

Pedersen concludes: "The main result of this analysis is the setting up of a small group of hæmorrhages with the easily recognisable sign of hæmatemesis in hospital. The lethality of this group is so high and it comprises so large a number of those dying from exsanguination that criteria for surgical intervention with a view to hæmostasis must be considered for this group."

We have therefore decided to operate only on patients who have (1) a proved or highly probable ulcer, and (2) a hæmatemesis while in hospital, and then (3) only if they are over the age of 40. In the last two years our group has dealt with some 380 cases of bleeding ulcer, of which 35 conformed with these criteria. Of the 35 patients, 12 were, for various reasons, not operated on; and 2 of these died (men of 42 and 69), both from loss of blood. Of the 23 who were operated on, 3 died—a woman of 63 and man of 73 from heart-failure, and a man of 73 from continued bleeding. Among the remainder which did not conform with Pedersen's criteria, 6 died from melæna, the youngest being aged 51 and the oldest 92, so that altogether there were 11 deaths.

In the same period we performed 319 partial gastrectomies for ulcer (including the bleeding ulcers) and lost 12 patients—a gross mortality-rate of 3·8%.

One of the principal difficulties, in our experience, is to establish the diagnosis of ulcer, particularly duodenal ulcer, in elderly patients with a very short history of a week or ten days. Somewhat reluctantly, we have had such patients taken to the X-ray department with a transfusion running; but in most cases this has been rewarded by the demonstration of an ulcer, and the patient has been operated on. In a few cases no ulcer could be seen radiologically, but gastrectomy was performed and the ulcer found. In one case, in a man of 69, no abnormality was found in the stomach or duodenum at laparotomy; the abdomen was closed, and he has had no further symptoms.

We have found that by following Pedersen's criteria we ensure that the most gravely threatened cases are operated on early, and at the same time we avoid doing a large number of "unnecessary" emergency gastrectomies.

Surgical Department A,
Bispebjerg Hospital, Copenhagen.

[1] Pedersen, J. *Gastroenterology*, 1949, 13, 597.

Sir,—When, in March, 1948, Sir Gordon Gordon-Taylor, lecturing to the Medical Society of Athens on the treatment of hæmorrhage from gastroduodenal ulcer, said that the case-mortality from this hæmorrhage amounted, on an average, to 10%, this statement appeared strange to most of us, and some of us even contradicted it. This Greek view is supported by Blackford, Smith, and Affleck,[1] who have reported that a great many physicians with a large practice have never met with a fatal case of hæmorrhage from gastroduodenal ulcer and therefore consider the mortality to be very low.

Since the mortality-rate of hæmorrhage from gastroduodenal ulcer is of vital significance from a therapeutic point of view, we have investigated the material available at the hospitals of Athens and Piræus, and we reported our findings in detail to the Medical Society of Athens on May 1, 1949. Briefly, our conclusions were as follows:

(1) Hæmorrhage complicated gastroduodenal ulcers in 1172 out of 4954 cases (23·65%). The only hæmorrhages that were counted were those for which the patients were being treated; so the actual proportion must be higher in view of the fact that the patients' individual histories could not be investigated, owing to various obstacles, including the destruction of many hospitals' records during and after the war. Thus it was impossible to ascertain, in each case of gastroduodenal ulcer under treatment for some condition other than hæmorrhage, whether hæmorrhage had occurred in the past.

(2) The incidence of hæmorrhage from gastroduodenal ulcers during the war (28·25%) was higher than the pre-war rate (12·16%) and somewhat lower than the post-war rate (33·92%), suggesting that the privations of the war period and other physical and emotional factors, and their post-war repercussions, have increased the tendency of ulcers to bleed.

(3) The age-incidence of hæmorrhage from gastroduodenal ulcers before, during, and after the war has not fluctuated appreciably, except that during the post-war period it seems to have increased in patients over the age of 45. In this period

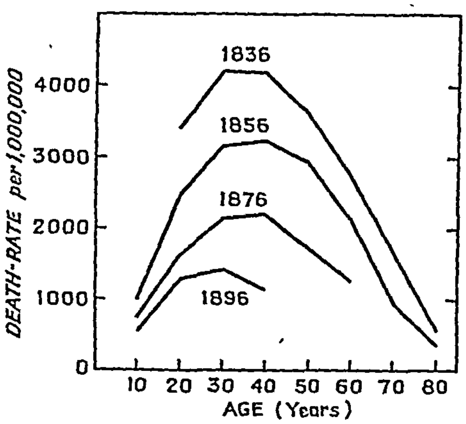
Letters to the Editor

TUBERCULOSIS MORTALITY

SIR,—It is well known that the age at which the death-rates from tuberculosis are at a maximum (apart from infancy) has been getting progressively older. The Registrar-General's figures for deaths of males from all forms of tuberculosis in England and Wales during the years 1851–60 show a maximum death-rate at the ten-year age-group 25–35; for 1881–90 the maximum is at age-group 35–45; and for 1931–40 at the age-group 45–55.

This aspect is the result of the usual method of examining mortality, which is to consider the death-rates over a calendar year or period of calendar years. It has, however, been shown by Frost,[1] using United States statistics, that a rather different picture is obtained if the death-rates are examined according to year of birth instead of calendar year; and the vital statistics of this country are found to show similar features—a fact which does not seem to have been fully appreciated here.



Each curve in the accompanying diagram shows, for England and Wales, the tuberculosis death-rates per 1,000,000 which have been experienced by a group of males born during the given period as they get progressively older. Curves are drawn for males born during the periods 1826–45, 1846–65, 1866-85, 1886–1905 (average years of birth 1836, 1856, 1876, 1896). The curves for the later years of birth are, of course, incomplete because the group of lives under consideration has not yet reached the advanced ages.

It will be seen from the diagram that the curves for all years of birth are of very similar shape and show no sign of the postponement of age of maximum mortality found in the case of death-rates by calendar year. It would therefore appear that every generation experiences its own mortality and that the *relative* variations with age are rather similar for all generations (i.e., the shape of all the year-of-birth curves is similar). Thus the year of birth seems to be a more fundamental function than the calendar year so far as tuberculosis mortality is concerned, and a generation which has experienced high tuberculosis mortality at the young ages continues to suffer from high mortality throughout life. In this light the progressive increase in the age of maximum (calendar year) mortality does not represent the postponement of maximum risk to later life but is rather the result of the higher rates experienced by the older lives in their young days. It would be incorrect to infer that young adults of today will experience higher tuberculosis death-rates in middle life than they are at present subject to; tuberculosis is still primarily a disease of youth. Female lives show somewhat similar features, although the picture is less pronounced and rather more confused than for males.

A full account of this investigation will appear later in the *Journal of the Institute of Actuaries*.

R. H. DAW.

Harrow, Middx.

ARTERIAL CALCIFICATION

SIR,—We have read with interest the article of March 4 by Sir Adolphe Abrahams and subsequent correspondence.

For the past two years we have been doing chemical analyses on arteries obtained post mortem. In confirmation of the work of others, we have found that the concentration of calcium in arteries which on gross and microscopic examination appear normal increases with age, or, more correctly, the logarithm of the concentration of calcium (and magnesium and phosphorus) increases with age. This is true for both the aorta and the internal carotid arteries. The concentration of minerals, like the concentration of lipids, also increases with the degree of atherosclerosis.

Of great interest are the cerebral arteries. The concentration of calcium (and magnesium and phosphorus) does not increase with age and, unlike the concentration of lipids, does not increase with the degree of atherosclerosis. In other words, cerebral arteries do not usually calcify. It would thus appear that such vague diagnoses as "hardening of the arteries of the brain" and "calcification of the cerebral arteries" are unjustified. These results support the suggestion of Wells [1] that calcification in atheromatous arteries may be a protective mechanism. It is possible that the lack of calcification in atheromatous cerebral arteries is a reason why such arteries are so liable to rupture.

DEOXYCORTONE WITH ASCORBIC ACID IN RHEUMATOID ARTHRITIS

SIR,—The difference between the excellent results reported in your columns in the treatment of rheumatoid arthritis with deoxycortone acetate and ascorbic acid (Lewin and Wassén 1949, Le Vay and Loxton 1949, Fox 1949, Loxton and Le Vay 1949, Douthwaite 1949, Robertson 1950, Fox 1950, Nashat 1950, Landsberg 1950, Le Vay and Loxton 1950, Hallberg 1950, Spanopoulos 1950, and Morelli and Pusateri 1949) and those obtained by the clinical members of the Empire Rheumatism Council Scientific Advisory Committee and Research Subcommittee (using the same substances and essentially the same technique) has prompted this letter.

The original proponents of this method of treatment claimed that "fifteen to thirty minutes later" (after the injection) "pain had practically disappeared and the mobility improved as much as the anatomical changes in the joints and muscular atrophy would allow. All the patients reacted in a similar way. In some cases the improvement was astounding. One of the patients was completely crippled by pain and contractures after rheumatoid arthritis for fifteen years: after *one* combined injection, she sat up with ease and moved her arms and legs about freely: all her pain had gone. . . . The effect lasted from two to six hours, occasionally more than twenty-four hours"—and occasionally "two or three weeks."

Such results are claimed also by the various authors mentioned above, from Poland, Cyprus, Naples, and Bagdad as well as from England. It is noteworthy, however, that such an experienced investigator as Spies (1949) as well as Hart and Starer (1949), Currie and Will (1950), and some of us (Kellgren 1949, Hartfall and Harris 1949, Fletcher et al. 1950, Kersley, Mandel and Jeffrey 1950) have already published results at variance with those described above.

The undersigned, each of whom has had experience in the assessment of "cures" in rheumatoid arthritis, have

PENICILLIN IN UNCOMPLICATED GONORRHŒA

SIR,—The article by Mr. Ambrose King and his colleagues, in your issue of April 15, is a salutary reminder that gonorrhœa is still a serious disease and still needs serious attention. Few would deny that in penicillin we have a specific cure for uncomplicated gonorrhœa. The difficulty is that it is impossible to determine the precise point at which cure has been achieved, and the possibilities of error are great.

Owing to the anatomy of the area, every case is, to a greater or lesser extent, a closed infection, which would account for the undoubtedly delayed response to penicillin therapy. It is a pity that local treatment has fallen into such disuse, because this is a valuable means of opening up and draining channels of infection. Even so, one wonders how many of the relapsed cases mentioned by Mr. King and his fellow-workers were penicillin failures.

It used to be taught—and I think the teaching still holds good—that the commonest causes of relapse were sexual indulgence, alcohol, and trauma. The physiological disturbance accompanying the first of these is quite enough to revive a dying infection. It would have been interesting to have known the part possibly played by alcohol as a cause of some of the relapses.

Queen Mary's Hospital for the East End, London, E.15.

F. G. MACDONALD
Venereologist.

GENERAL PRACTICE TODAY

SIR,—I believe that a partial return to the apprentice system would do a great deal to remove the dissatisfaction which is apparent in general practice today. As a representative of a group of students has pointed out in your columns,[1] it is useless and unfair not to let them know what they are in for when they enter general practice. This is one of the root causes of frustration in later years. The rarefied atmosphere of the teaching hospitals, and the privileged conditions of work in hospitals generally, do not prepare them psychologically for the wear-and-tear of treating patients in their homes, or in surgeries without elaborate equipment and ancillary services. They do not appreciate how much ill health is due to environmental factors.

I feel sure that a short period of time spent in company with a general practitioner would be time very well spent from the student's point of view. But it would be even more beneficial and stimulating for the general practitioner. Everyone who has had any experience of teaching undergraduates knows what pertinent questions they ask, and how salutary it is to have them challenge ideas which are not well founded. They would provide living links with the teaching hospitals and with the new ideas from which the G.P. feels himself to be irrevocably severed, and would stimulate, indeed help, him to make the best possible use of his facilities, limited though they are. At the same time the student would learn to rely more on clinical methods, and less on laboratory findings.

Edgware General Hospital, Middlesex.

M. D. BABER.

SIR,—So far everyone seems to accept what the Act has done to the general practitioner. It has divided the profession into the sheep and the goats—there is no process of metamorphosis. Once a young man has become a G.P. he is excluded from any active clinical part on the hospital side. Any bent that he has—be it medicine, surgery, radiology, pathology, obstetrics, or anything else—is allowed to die out. There are no part-time clinical assistantships through which the G.P. might graduate to specialist status. The very system of prespecialist training is evolving the man who "knows more and more about less and less."

Compared with Army medicine the present service is stultifying. In the Army every medical officer has opportunities for acquiring knowledge in every branch of medicine and is actively encouraged to take an additional appropriate diploma or degree, on which hangs definite professional advancement in the Service. Not so in "civvy street." You may have a specialised degree or diploma and have vast experience to match, but if you are a G.P. you are like "Barney's bull."

In case I might be thought an iconoclast let me offer a very little constructive advice:

1. The colleges should not admit for their higher diplomas those for whom a career in that specialty is not open. Each candidate should be responsibly sponsored.
2. The hospitals should throw open their doors and allow G.P.s to become trainees in the specialties they favour.

Many would not "make the grade," but I think that a kindlier atmosphere would pervade the profession, and it would be more difficult to distinguish between the sheep and the goats.

Longtown, Cumberland.

R. RUTHERFORD.

PROPHYLACTIC INOCULATIONS AND POLIOMYELITIS

SIR,—Dr. McCloskey and other workers in this field have certainly raised an issue worthy of the fullest investigation.

I have one or two questions to ask about his article in your issue of April 8. Apart from the obvious statistical difficulties to which you refer in your leading article of the same date, I think we all would be interested to hear what diagnostic criteria were applied to the 31 cases occurring after inoculation. In how many of these cases was the virus demonstrated? Did they all show characteristic changes in the cerebrospinal fluid?

In an issue of this magnitude we should be certain beyond all possible doubt that these were cases of poliomyelitis, and not possibly some form of peripheral neuritis.

Chester.

B. G. GRETTON-WATSON.

CONTINUOUS DRIP TREATMENT OF PEPTIC ULCER

SIR,—I should be glad if you would allow me to amplify a few points which have arisen regarding my article in your issue of March 11.

My experiments were designed to see if alkali—magnesium bicarbonate—would give results equal to milk with regard both to the neutralisation of gastric contents and to the relief of pain, with the presumption that if it did so, then it furthered healing. The answer here was that it did.

Secondly, the actual pH achieved, along with clinical details, was shown on a table, which was unfortunately too large to be published. In 39% of the samples the pH of the aspirated sample was less than 2·0. This is not nearly as good as theoretical considerations would suggest as desirable. Nevertheless the relief of pain and clinical results suggest that the therapy is effective. Incidentally, where radiological examination indicated that healing had taken place, this was confirmed by gastroscopic examination except in one case.

This raises the question of how the drip does good. Perhaps our sights have been set too high and only small alterations in pH are necessary to produce healing. It must be remembered that the pH scale masks the tenfold difference between pH 1 and 2. Perhaps, again, the therapeutic effect has nothing to do with reduced acidity.

In reply to Dr. Houlder (March 25), I should like to affirm that the drip is less trouble than the more conventional dietetic régimes in hospital practice and, I believe, also in general practice after a little extra trouble by the doctor at the start of treatment.

---

[1] Hart, J. T. *Lancet*, April 15, p. 737.

out of 537 cases of ulcer hæmorrhage 183 were in persons aged under 45 and 262 in persons over this age.

(4) The average case-mortality in the cases observed by us was 12·96%.

The mortality was lower in persons under 45 before the war (4·16% under 45, against 12·08% over 45), during the war (4·55% and 10·89%), and since the war (0·93% and 6·33%). A comparative survey shows no increase worth mentioning in the case-mortality during the war over the pre-war rate, whereas both the pre-war and war-time rates were considerably higher than the post-war rate. This fact can probably be explained by the pre-war practice of dietetic abstinence, which had to be continued during the war from lack of light foods, the only ones which could be given after a strict milk diet (when milk could be had) to ulcer patients. In the post-war period, the modern practice of earlier and more generous feeding of patients and the more extensive use of blood-transfusion, have lowered the death-rate from gastroduodenal hæmorrhage.

If we accept that the average case-mortality from hæmorrhage from gastroduodenal ulcer in Greece is (in round figures) 13% and that the fatal cases are mostly in persons over 45, it follows that in patients over this age operation is clearly indicated when the bleeding is severe, is undoubtedly due to an ulcer, and continues or recurs in spite of conservative treatment (mainly blood-transfusion).

State General Hospital, Athens.

PREGNANCY AND PULMONARY TUBERCULOSIS

SIR,—Dr. Midgley Turner is to be congratulated on his careful accumulation of facts and their varied presentation in his article of April 15. His findings are generally similar to those of others who have looked into this problem in recent years. His evidence regarding the "danger periods" is particularly striking.

Whilst studying a similar large group of cases a few years ago, we also became aware of "danger periods." Our figures[1] were very similar to those in table IV of Dr. Turner's article; but, as in that table, the numbers were not regarded as sufficient to give conclusive evidence. We found that relapses and deaths in patients with both active and quiescent pulmonary disease occurred almost invariably during the first three months of pregnancy, or within a month or six weeks of delivery or termination of pregnancy. A caution is perhaps necessary here; the "month of onset" of tuberculosis is not always easily determined. Routine X-ray observation of pregnant women and others may discover new lesions which appear before more spectacular clinical symptoms later draw attention to them.

In contrast to the findings in the pregnant patients, relapses and deaths in our non-pregnant control groups were more evenly distributed throughout the period of observation (15 months). The total relapses for both groups for the same period were similar. Whether or not the hormonal changes during pregnancy influence the time of relapse in a patient with established disease, it is certain that the over-all effect is not different from what would be expected had they not borne children. It would therefore seem illogical to advise termination of pregnancy at any time when it is known that the risk of endogenous relapse is no greater than would be expected had the patient not been pregnant. It is interesting that in the literature on pregnancy and tuberculosis written during the past forty years, physicians who normally see their patients throughout pregnancy take a more favourable view of the outcome than do obstetricians, who are more likely to follow the patient closely at delivery and during the puerperium —one of the "danger periods."

The main evidence brought forward by Dr. Turner in support of the "danger periods" concerns the onset of tuberculous disease rather than relapse of established disease. Might it not be that hormonal changes have a greater influence in lowering the local tissue defence to primary invasion of the tubercle bacillus rather than in generally lowering resistance in those already infected? There is no doubt that progressive disease resulting from primary infection in adult life is being recognised more frequently.

Finally, we would endorse Dr. Turner's hope that physicians will find time to investigate this problem further, in order to get a better understanding of what, for want of a better term, we must still call "resistance," be this biochemical or biophysical.

WHAT MAKES A GOOD HOSPITAL?

SIR,—I have read with great interest the article of April 1 (p. 633) on this subject. While fully subscribing to the writer's views, so well expressed, I feel that he could have included the spiritual element. Many of our hospitals, especially such ancient institutions as St. Bartholomew's, which he mentions, were founded on religious ideals. Just as hospitals have their medical, nursing, and administrative staffs, so they should have their religious advisers, who may be of considerable comfort to patients in low waters. This is especially true of our large mental hospitals. There should be a close alliance between priest and physician as many patients' ills are spiritual as well as physical.

Referring to the administrative side, I feel that the greatest care is required in the appointment of a hospital secretary, house-governor, or whatever be his official designation. The appointment of a man of refinement and tact, who does not seek to wield totalitarian sway over the personnel, will avert avoidable friction within the hospital. The need here is for an effective combination of brains and character.

Long Grove Hospital,
Epsom, Surrey.

TREATMENT OF HERPES ZOSTER

SIR,—I read with interest, but also with despondency, your leading article last week. Although among the manifold remedies you mentioned you did mention physiotherapy, I am surprised that ultraviolet irradiation, which has definitely a specific and curative effect in this disease if applied in its early stages, was not referred to.

Authors of books on ultraviolet irradiation are all agreed on this. The first edition of *Artificial Sunlight and its Therapeutic Uses*, by the late Dr. F. Howard Humphris, appeared in 1924. In this and subsequent editions the following statement is made: "The treatment of herpes by ultra-violet irradiation is spectacular in its success."

As a general practitioner I treated some twenty cases of herpes zoster with ultraviolet irradiation. On an average six treatments were required. None of these patients were incapacitated from work; pain was relieved within two days; there was no subsequent scarring and no intercostal neuralgia. I am confident that with accurate technique similar results can invariably be achieved. Down the years I have treated innumerable cases of intercostal neuralgia following herpes.

Unfortunately, in medical schools and textbooks of medicine ultraviolet rays in the treatment of herpes is never mentioned, so that the general practitioner is almost entirely ignorant of the efficacy of such treatment. Intercostal neuralgia would never occur after herpes zoster if ultraviolet irradiation was always applied.

[1] Stewart, C. J., Simmonds, F. A. H. *Brit. med. J.* 1947, ii, 726.

may be suggested that, given the opportunity, research forms a part of his duties, especially in the laboratory. On the other hand it may be argued that a registrar who burns the midnight oil in research deserves encouragement in contrast to his colleague who may adhere closely to his hours of duty and spend his leisure hours in remunerative activities such as, for example, writing his autobiography or a textbook. In any case, if these sums cannot be paid to whole-time salaried workers, what use is to be made of them? Should they be spent in the purchase of apparatus? To whom would such apparatus finally belong? Should they be consolidated so that the aggregate sum will support a whole-time research-worker? Is such consolidation legally permissible?

Full-time salaried doctors did not spring into existence with the introduction of the National Health Service, and it used to be common practice for such men to receive personal grants for research, although, of course, salaries were then much lower.

It would be convenient if an authoritative ruling were given on this point, and when that ruling is given consideration should be given not only to the letter of the law as affecting registrar's salaries, but also to the possible effect of the ruling on the future of medical research.

CARDIAC EFFECTS OF P.A.S.

SIR,—Dr. Cayley, in his article of March 11, records cardiac irregularity in three patients under treatment with *p*-aminosalicylic acid (P.A.S.).

I performed electrocardiography (E.C.G.) on a young man seriously ill with tuberculous peritonitis, who had had massive doses of P.A.S. for ten days and whose pulse-rate suddenly fell to 50 per min. from the usual high rate of 100–120 per min. Study of the E.C.G. tracing revealed auricular fibrillation and apparent complete auriculoventricular block. The patient died before serum-potassium estimation had been performed. In retrospect it appears that this may well have been a further example of the effect of P.A.S.

B. S. LEWIS.

THE OPEN WOUND IN TRAUMA

SIR,—It had to come. The debate remained undecided at the end of the war. Tribute was paid to Trueta for his contributions to war surgery, but many surgeons continued to criticise his methods much in the same way as Mr. Essex-Lopresti has done in his article last week.

Trueta's technique is not based wholly on the idea that all wounds are contaminated (although one must make this assumption in the case of war wounds). The five points he emphasises are all important, and any deviation from them in any respect cannot be described as his method. Contamination is only part of the story. Equally important is the presence of non-viable tissue, especially muscle, which is easy to detect if it is dead: and every bit of ischæmic muscle and hæmatoma must be excised in every part of the wound, which must be enlarged in each direction sufficiently to enable the surgeon to explore every nook and cranny. It is fair to say that the 10 cases which became infected in Birmingham were not treated by Trueta's technique. I have had the opportunity of working with, and seeing the cases of, Professor Trueta for some years, and I can categorically state that no wound or compound fracture treated by him ab initio ever became infected; osteomyelitis was therefore unknown.

Even more important are the unfortunate effects of this article. It is admirable to hear that primary skin cover has been successfully applied in compound fractures treated in Birmingham; but I am sure that the pursuit of this precept would be highly dangerous in less skilled hands, since, owing to inadequate excision, limbs, and perhaps lives, would be lost owing to tissue tension and gangrene.

Trueta has never said that wounds are to remain open. Even before the days of penicillin he was closing his wounds after periods varying with conditions, and since the appearance of penicillin he has been getting early skin cover over wounds which, I must repeat, are never infected if he carries out the primary wound treatment. His teaching, properly applied, means the complete absence of sepsis, early skin cover, and the minimum time for the restoration of optimum function. Critics should understand Trueta's technique before trying to saddle it with failures which do not occur in the hands of Trueta himself.

St. Margaret's Hospital, Swindon.

F. LOUIS.

TREATMENT OF DISSEMINATED CUTANEOUS HERPES SIMPLEX WITH AUREOMYCIN

SIR,—Baer and Miller[1] treated with oral and local 'Aureomycin' two adult cases of disseminated cutaneous herpes simplex (Kaposi's varicelliform eruption). They found that the aureomycin produced rapid healing of the skin lesions and prevented the development of further lesions. Bereston and Carliner[2] also reported a favourable response to aureomycin in an unusually severe case of disseminated cutaneous herpes simplex. We were encouraged by these reports to treat with aureomycin two infants with this condition.

CASE 1.—A girl, aged 11 months, had had atopic eczema since the 10th week of life. Three days before admission on Jan. 15, 1950, she became febrile and the eczematous areas became œdematous and were covered with an eruption of small umbilicated vesicles which also extended a short distance on to previously normal skin. A history was elicited of contact during the previous week with an aunt who was suffering from labial herpes. A clinical diagnosis of Kaposi's varicelliform eruption was made and treatment with oral aureomycin (125 mg. 8-hourly) and intramuscular penicillin (100,000 units 8-hourly) was initiated. Two days later new vesicles continued to appear on and near the eczematous areas. The dose of aureomycin was increased to 150 mg. 6-hourly. Occasional further vesicles developed during the next day or two. The child made a satisfactory recovery; no secondary infection developed.

The serum titre of herpes antibody increased from 2 units in the acute phase to 32 units in the convalescent phase (Dr. J. A. Dudgeon).

CASE 2.—A boy, aged 7 months, who had had atopic eczema since his 3rd month, was admitted to hospital on Feb. 8, 1950. The clinical appearance on admission and the course of the disease differed very little from the previous case and new vesicles continued to appear 2–3 days after the administration of aureomycin was started. An attack of severe diarrhœa was attributed to the aureomycin since no other cause was discovered.

Virus-antibody estimations were not undertaken.

In neither case did the aureomycin prevent the continued development of new vesicles, nor did it obviously modify the natural course of the herpetic infection. Any benefit derived from the aureomycin is to be attributed to the control of secondary bacterial infection of the vesicles. The course of the disease in these two infants treated with aureomycin did not differ from that of two similar cases previously treated by one of us with penicillin alone.

Our observations in these two cases lend no support to the claim that aureomycin has any specific value in the treatment of disseminated cutaneous herpes simplex.

2. Bereston, G. S., Carliner, P. E. *Ibid*, p. 13.

I used no controls, since previous articles, which I quoted, had shown quite definitely that dietetic régimes do not maintain adequate neutralisation of the gastric contents throughout the 24 hours.

Worcester. A. M. CLARK.

THE CARNAGE ON THE ROADS

SIR,—The driving test may have its drawbacks, but it is a step in the right direction. I suggest extending the scheme by the institution of a probationary period for one year following the test. Such drivers would carry "P" plates, and since the majority of accidents are due to speed "P" drivers would be prohibited from exceeding 30 m.p.h. The penalties for exceeding this limit would be the same as in a built-up area for the first two offences, but the third would automatically result in a return to learner-driver conditions and the cycle would begin again. The main advantage of this scheme is that the curbing of the instinct to speed would become almost automatic, and the existing machinery is adequate to deal with the administrative side.

Preston. E. B. LOVE.

VITAMIN B_{12} IN IDIOPATHIC STEATORRHŒA

SIR,—May we correct a misquotation in last week's article by Dr. Tuck and Dr. Whittaker? We stated[1] that "the percentage fat absorption defect of less than 90% [not 95%] could not be regarded as normal" and "if the figure was between 85 and 90 and the presence of a defect not closely supported by other clinical manifestations, reinvestigation was made." Only 2 [not 4] of our cases had a percentage absorption of 90%, one of which was reported to have a second balance of 80% absorption. Usually a single three-day balance is adequate for diagnosis, but in patients in whom the defect may not be marked we employ continuous or repeated three-day balances.

The two excellent papers and interesting leading article last week afford timely emphasis on the occurrence of a fat-absorption defect in certain macrocytic anæmias. We would strongly support the observations made that the presenting symptoms and the macroscopic appearances of the stools may be no guide to the presence or absence of steatorrhœa, as indeed was originally pointed out by Samuel Gee and, more recently, by many other workers.

In our first 100 cases of idiopathic steatorrhœa, intestinal disturbance was the presenting symptom in less than half, while of the remainder 10 were free from intestinal symptoms and had macroscopically normal stools. The latter group contained a number of patients with a macrocytic anæmia which was only distinguishable from pernicious anæmia by virtue of a fat-absorption defect and the failure to attain normal blood-values with adequate therapy with liver extracts.

We have found that megaloblastic anæmias associated with idiopathic steatorrhœa invariably react favourably to folic acid, but of 9 cases studied in detail none at any time produced normal absolute values and in only 3 did any of the subsequent red blood-cell counts rise above 4,200,000 per c.mm., and reinforcement with oral liver preparations was without further effect. Although some patients will respond with a maximum reticulocyte response following parenteral vitamin B_{12} (we have studied 3 such cases), other patients who have similar hæmatological findings and definite fat-absorption defects fail completely to react.

We are still of the opinion expressed in 1948[2] that the varied hæmatological responses which may be found in steatorrhœa are manifestations of deficiencies caused by the underlying and hitherto unexplained defect, and that they vary from time to time in any given patient. Nevertheless, the underlying defect can be favourably influenced by strict adherence to a high-protein low-fat diet, and this must remain one of the foundations of the treatment of these cases.

THE GLASGOW SMALLPOX OUTBREAK

SIR,—The recent outbreak of smallpox at Glasgow, now happily ended, is of more than usual interest, and it is not surprising that it has aroused more than usual concern. Some important lessons taught by it may be emphasised:

1. The truly disastrous consequences which may result from "missed" cases of smallpox. In view of the heavy mortality attending the outbreak no further emphasis on this is called for.

2. The effect of vaccination and revaccination in "masking" the nature of the disease and so leading to "missed" cases. Had the well-vaccinated lascar sailor who was the cause of this outbreak been unvaccinated, it is in the highest degree unlikely that his illness would have been unrecognised, or at least unsuspected; precautions would have been taken, the case isolated, and contacts vaccinated, and presumably six deaths would have been prevented. True, he would have had a much more serious attack and he might even have died, but six lives would have been saved. This is an aspect of the vaccination question which has been too long ignored.

3. The undesirability, when smallpox breaks out, of at once resorting to mass vaccination. We now know that in this latest outbreak, as in the outbreak in Glasgow in the summer of 1942 and in that in Edinburgh a few months later, spread of infection had ceased before mass vaccination was begun, so could have had nothing whatever to do with the cutting short of the outbreak. The price of a mass-vaccination campaign has to be paid in injury to health whether it has any effect or not in preventing the spread of the disease. Vaccination is not a trivial operation unattended by any danger to health. Amongst the 300,000 persons estimated to have been vaccinated in the Glasgow area, and not counting the many more thousands vaccinated in other parts of the country, we may assume that there will be some (an unknown number) who will have suffered permanent injury to health, and a much larger number who will have suffered at least temporary injury. In the Edinburgh mass-vaccination campaign of 1942, there were 22 cases of postvaccinal encephalitis reported, 8 of which proved fatal, making a total of 10 certified deaths. Let us hope that less unfortunate results will follow this latest scare.

4. The desirability of all doctors and nurses not only being vaccinated but of being kept immune by repeated vaccination as often as necessary. The safest rule would be once a year as a matter of routine. Any unpleasant reactions would then be negligible or indeed non-existent.

Leicester. C. KILLICK MILLARD.

USE OF HOSPITAL RESEARCH FUNDS

SIR,—The position of medical research-workers under the National Health Service Act has not yet been fully clarified. There is one question which perhaps might readily be settled, but on which no authoritative ruling has been given.

Many institutions have relatively small sums of money available earmarked for research as a result of gifts or bequests. Is it permissible for these moneys to be paid to doctors who are whole-time servants under the National Health Service?

The group most affected are registrars. It appears to be established that whole-time registrars cannot receive fees of any kind. If they carry out research outside their hours of duty, is it in order for them to receive payment from research funds? The arguments for and against such payments are very evenly balanced. On the one hand, the registrar is assumed to be paid the full amount suitable for his age and duties, and it

Obituary

WILLIAM HENRY BUTTER STODDART

M.D. LOND., F.R.C.P.

GENERATIONS of students from the Royal Free Hospital, Westminster Hospital, and St. Thomas's Hospital will remember with affection W. H. B. Stoddart, who during the first quarter of this century lectured to them on mental diseases.

He was the son of William Stoddart, a surveyor, and in the '80s attended the City of London School, where the famous Mr. Abbot was headmaster. Later he went to University College and to University College Hospital, where he qualified in 1893, taking his M.B. the following year and proceeding to his M.D. in 1894. After holding house-appointments under Frederick Roberts at U.C.H., he became clinical clerk to Hughlings Jackson at the National Hospital, Queen Square. W. H., who joined him there as house-physician in 1895, recalls him as "balding even then at twenty-seven, 6 ft. 3 in. tall, with a most genial and kindly temperament, and a fine baritone voice. He was very musical, a good pianist, and fond of singing, and I would often get him to play for me some of the Beethoven sonatas, and on one or two occasions we would venture on trios, aided by my violin, and Ronald Carter, then clerking for Gowers, with his 'cello. At Christmas '95, we produced some theatricals in the outpatient waiting-hall; stage-managed by Dr. Walter Colman, our pathologist, in which many of the nurses took part, in costume, and Stoddy's singing was a principal feature."

After leaving the National Hospital in 1896, Stoddart was clinical clerk at Bethlem Royal Hospital for some months before taking up an appointment as pathologist at Prestwich Mental Hospital in Lancashire. In 1898 he returned to Bethlem Hospital as assistant physician under Percy Smith, Hyslop, and Maurice Craig. Later he succeeded Craig as physician-superintendent, and in 1908 he was elected F.R.C.P. He remained at Bethlem Hospital until 1914. Meanwhile he had received his teaching appointments at the Royal Free and Westminster Hospitals. Later he was appointed to a similar post at St. Thomas's and elected to the staff as physician.

In 1901 he had been awarded the Gaskell gold medal of the Medico-Psychological Association, and at the International Medical Congress in 1913 he read a paper on Acute Confusional Insanity. His colleagues found it natural for Stoddart to veer from pure neurology to psychiatry, for he had always been attracted by the theoretical side of neurology as taught by Hughlings Jackson, and later he became an ardent disciple of Freud's theories and practice. For his Morison lectures to the Royal College of Physicians of Edinburgh in 1915 he chose as his subject the New Psychiatry. The early editions of his *Mind and its Disorders*, which first appeared in 1919, were then the best of their kind. Later editions were somewhat confused by the inclusion of psychopathological ideas which he had not quite assimilated into his thinking. For many years he was treasurer of the British Psychological Society and of the British Psycho-Analytical Society, and he also served on the council of both these bodies. J. R. writes: "A tall portly man, vastly oval in body—viewed from whatever angle—and oval in head, Stoddart arrayed himself in morning-coat and top hat (grey frock coat and grey topper in summer) to lead his students round Bethlem or teach them in an outpatient department. Placid almost to indolence in manner, detached yet friendly, he soon got his patients to forget the huddle of students and give their histories. Despite his casual manner little escaped his small lively eyes; despite his drawling speech he conveyed to his students something of his enthusiasm for new ideas. He was the butt of many jokes, at which he was much amused, and his colleagues professed to take him less seriously than in fact they did; this did not disturb him, for he knew and they knew that his clinical experience and acumen were considerable and were always at their service. His genial philosophy was a support not only to others but to himself in time of trouble; when very ill after an operation he said as he lay exhausted, 'Death is sweet, but dying is bloody.' Nevertheless he was even then cheerful and could not but turn the bedside conversation into a pleasant social occasion. Those who stood closest to him will mourn the loss of a friend whose good humour and good nature flowed from his being at peace with himself, so he made others feel at peace with the world."

Dr. Stoddart married in 1909 Mrs. Rosa Johnstone, who was matron of the Bethlem Royal Hospital. After her death in 1945 he continued to live with his stepdaughter in London until his death early this month.

FERDINAND SIMEON LE QUESNE

V.C., M.R.C.S.

Lieut.-Colonel F. S. Le Quesne, who died on April 4 at Clifton, won his V.C. in 1889 in operations against the Chinns in Burma. During an attack on the village of Tartun he remained close to the enemy's stockade for a quarter of an hour dressing the wounds of a lieutenant of the Norfolk Regiment, who was lying within five yards of a loophole from which the enemy was maintaining continuous fire. Later, while tending other casualties, he was himself severely wounded.

Born in 1863 in Jersey, the son of Lieut.-Colonel Giffard Le Quesne, he qualified from King's College Hospital in 1886 and received his commission in the Army the same year. Colonel Le Quesne also served with the Chin Lushai expedition in 1890, and in South Africa and Cape Colony at the beginning of the century. During the 1914–18 war he served in France. He retired in 1918. A fine shot, he was also in his youth a keen rackets and tennis player.

RONALD RILEY

B.A. CAMB., M.R.C.S.

Dr. Ronald Riley, who died at Broadstairs on April 3 at the age of 49, had been in practice in the Isle of Thanet since 1930. The younger son of William Riley, he was educated at Blackburn Grammar School and Sidney Sussex College, Cambridge. He qualified in 1923, and held appointments as house-surgeon, house-physician, and medical superintendent at his own hospital, St. Mary's, and as house-physician at the Hospital for Sick Children, Great Ormond Street. Deciding on general practice, he went into partnership at Broadstairs with the late Dr. E. G. Moon, likewise a former student of St. Mary's. He rapidly built up a large and interesting practice, including work for preparatory schools, convalescent homes, hospitals, and infant-welfare centres. His general and special training had fitted him well for this work, and he did it with confidence and assiduity. In 1934 he was appointed honorary physician to the General Hospital, Margate, and he was senior physician from 1945 until his retirement from the staff last October. He was medical officer of a number of convalescent homes for children, among them the Yarrow Home of the Westminster Hospital, the Metropolitan Home, the Daughters of the Holy Cross Convent, the Red Cross Auxiliary Hospital, and the Shaftesbury Home for Children, Kingsgate. In 1940 he was appointed physician in the E.M.S. and stationed at the Minster Hospital, Isle of Sheppey; but in 1941 he was transferred back to the General Hospital, Margate, and was able to do part-time work in his practice. This proved arduous and often dangerous, but he found time to enter into many welfare activities in his town, as well as being a medical officer of the Home Guard and the Air Training Corps. After the war he interested himself in the revival of Broadstairs and worked hard as a member and chairman of the Chamber of Commerce. A prominent Freemason, he was past master of two lodges. He was also vice-president of the Broadstairs Sailing Club, and one of the original owners of the Foreland class of boats.

R. W.-S. writes: "Ronald Riley had a quiet charm and dignity of manner. He was a very kind and courteous general-practitioner physician, unsparing of himself in consideration for his patients, and a most loyal colleague; it was a delight to meet him in consultation because he always brought common sense to bear on the problem. He remained a true student of St. Mary's, seeking expert advice from his old teaching hospital in any difficult case. A devoted husband and father, the happiest times of his life were when he was surrounded by his family."

He married, in 1933, Patricia Aline Twiss, and leaves three sons.

FIRST OBSERVATION OF ANTIBIOTIC ACTION ?

SIR,—Historians of science are well aware of the difficulty of ascertaining the first observations of many natural phenomena. When the climate of opinion becomes favourable, or when there is an advance in technique, similar observations are frequently made independently and almost simultaneously by several workers.

Attention has already been drawn, for example, to the reference by Tyndall in his paper on the Optical Deportment of the Atmosphere (1876) to the antibiotic action of "*Pencillium glaucum*" on bacteria,[1] and Tyndall's observations are the earliest noted by Florey[2] in a recent historical review. Observations on this phenomenon were, however, made by the versatile William Roberts,[3] of Manchester, during careful "Studies on Biogenesis" carried out during 1872–73. In a paper published in 1874[4] describing his results (later considered at length by Tyndall[5]), Roberts stated his views very clearly in these words, which afford an early, if not the earliest, example of the use of "antagonism" in this connection :

> ". . . the growth of fungi appeared to me to be antagonistic to that of *Bacteria* and *vice versa.* I have repeatedly observed that liquids in which the *Penicillium glaucum* was growing luxuriantly could with difficulty be artificially infected with *Bacteria* ; it seemed, in fact, as if the fungus played the part of the plants in an aquarium, and held in check the growth of *Bacteria,* with their attendant putrefactive changes. On the other hand, the *Penicillium glaucum* seldom grows vigorously, if it grows at all, in liquids which are full of *Bacteria.* It has further seemed to me that there was an antagonism between the growth of certain races of *Bacteria* and certain other races of *Bacteria* . . . when an organic liquid is exposed to the contamination of air or water," he continued, ". . . There is probably . . . a struggle for existence and a survival of the fittest. It would be hazardous to conclude that because a particular organism was not found growing in a fertile infusion, that the germs of that organism were really absent from the contaminating media."

SECULAR TRENDS AND BLOOD CHANGES

SIR,—It has been demonstrated[6] that in normal individuals horizontal rest for 30 minutes produces a mean fall in plasma-protein of 0·35 g. per 100 ml. ($p < 0{\cdot}1\%$). An experiment designed to eliminate variation due to time showed that bed rest for 48 hours produced a mean fall of 0·65 g. per 100 ml. ($p = 1{\cdot}0\%$). Under standard conditions of activity, posture, diet, and blood-sampling, changes occurred during the hours of 7 A.M.–2 A.M. in Hb, hæmatocrit, plasma-protein concentration, and erythrocyte-sedimentation rate (E.S.R.), of twenty normal individuals. Variance analysis of the data showed that many individuals have a true diurnal rhythm (significant diurnal variation) in Hb, hæmatocrit, and plasma-protein.

In the case of the first two variates this consists in a statistically significant fall during the day with a rise sometime in the evening or the early hours of the morning. In the case of the plasma-protein, changes occur during the day but are of a random nature. However, a statistically significant fall occurs after 10 P.M.–midnight. In the case of the E.S.R. no true diurnal rhythm is present, but on any particular day a group of individuals show a significant variation during the day, suggesting that external factors—possibly the weather—may be concerned.

Under similar standardised conditions changes occur in periods longer than one day in the variates described. In the case of Hb, and hæmatocrit, variance analysis of data obtained from a group of eight normal individuals revealed statistically significant changes during the same consecutive 8-day period. Possibly weather changes (indoor or outdoor climate) may again be concerned. Elimination of this time-factor as a cause of variation in blood constituents (or in any physiological function) requires carefully controlled experiments.

It is still widely accepted that the concentration of blood constituents is fixed and does not change appreciably over various periods of time. Hence changes occurring during the period of an experiment (posture, bed rest, change in water balance, drug or surgical treatment, and so on) are often assumed to be causally related to the effects of the experiment itself. The interesting paper of March 25 by Miss Widdowson and Professor McCance shows that Hb, hæmatocrit, and plasma-protein fall after 2 hours' rest in bed, with a return to the original level after a further 3 days of bed rest. Although it is not clear from the text, it appears possible that the test subjects were examined over the same 2-hour and 3-day period. In such a case the fall in Hb and hæmatocrit after 2 hours may be due, at least in part, to diurnal change rather than to the horizontal posture, and the rise after 3 days to day-to-day variation and again partly or wholly unrelated to posture or inactivity. The red cells (as measured by Hb and hæmatocrit) and plasma-proteins appear to be independent variables, and recent work[7] suggests that neither may be an accurate index of changes in plasma-volume or even in the direction of change.

London, N.2.

E. T. RENBOURN.

Medicine and the Law

Delayed X-ray Report

A 7-year-old child fell from a swing in a playground in Clapham on March 8 and came home with a grazed forehead and a bleeding nose. Her mother took her next day to the Weir Hospital, Balham. An X-ray examination was made at once ; but, owing to the illness of both the radiologist and the radiographer, the films were in arrear and a report was not made until March 20, when a small fracture of the front of the skull was revealed.

Meanwhile, the mother, according to her evidence at the inquest, had made four inquiries about the result of the examination. After the fourth inquiry, she said, she was told that the X-ray result was clear, but that if she was still in doubt about anything she was to bring her daughter back to the hospital. She took the child to her own doctor, who advised her to put the child to bed. She followed this advice ; on the following morning the child "seemed to be having a fit." The child was admitted to the Weir Hospital, and was removed thence to another hospital where she died next morning of meningitis, sixteen days after her accident.

A pathologist told the deputy coroner that, if the child had been admitted to hospital with the fracture immediately after her fall, she would probably have been discharged before the symptoms of meningitis were suspected. The deputy coroner, who recorded a verdict of accidental death, observed that, had the findings of the X-ray examination been known earlier, steps would have been taken which might have prevented the child's death.

University of London

On Wednesday, May 31, at 5.30 P.M., Mr. Ernest Baldwin, PH.D., who has lately succeeded Prof. J. Z. Young, F.R.S., in the chair of biochemistry at University College, will deliver his inaugural lecture. He is to speak on the Biochemical Approach to Biological Organisation.

On Tuesday, June 27, at 5.30 P.M. at the London School of Hygiene, Keppel Street, W.C.1, Dr. C. J. Watson, professor of medicine in the University of Minnesota, will speak on Porphyrin Metabolism and Porphyria.

University of Leeds

At a congregation to be held on May 19, an honorary degree will be conferred on Dr. W. N. Pickles.

National University of Ireland

Dr. Kieran McGrath has been appointed to the chair of dental surgery at University College, Dublin.

Royal College of Surgeons of England

On Wednesday, May 3, at 5 P.M., Dr. P. D. Wilson, professor of orthopædic surgery, College of Physicians and Surgeons, New York, in the Robert Jones lecture will describe his Experience with the Use of Refrigerated Bone in Surgical Procedure.

Royal College of Obstetricians and Gynæcologists

On Friday, May 19, at 5 P.M., Dr. Linton Snaith will deliver at the college the biennial scholarship (sterility) lecture, on Habitual Abortion. Tickets may be had from the secretary of the college, 58, Queen Anne Street, London, W.1.

Almroth Wright Lectures

On Monday, May 8, at 5 P.M., at the Wright-Fleming Institute, St. Mary's Hospital, London, W.2, Prof. Alexander Haddow, will give the first of six Almroth Wright lectures. The other lecturers will be Prof. Perrin H. Long, Mr. A. T. Glenny, F.R.S., Dr. A. A. Miles, Mr. C. D. Darlington, F.R.S., Prof. F. M. Burnet, F.R.S. Further particulars will be found in our advertisement columns.

Oliver Memorial Fund

An award of £50 will be made from this fund to a British subject for original work or service in connection with blood transfusion. Applications must be sent before June 30, to F. W. Mills, Esq., National Provincial Bank Ltd., Holborn Circus, London, E.C.1.

Research Scholarships in Obstetrics and Gynæcology

The council of the Royal College of Obstetricians and Gynæcologists will shortly award Leverhulme research scholarships. Forms of application can be had from the secretary, 58, Queen Anne Street, London, W.1, and should be returned by July 1.

Appointments for Outpatients at St. Mary's Hospital

An appointment system for new outpatients will come into operation at St. Mary's Hospital, London, W.2, from May 1. Appointments may be made by telephone message to Ambassador 2241; by letter addressed to the appointments clerk at the hospital; or by the personal call of a patient, at the outpatient department of the hospital, with a letter of introduction to the consultant concerned. A letter of introduction should always accompany the patient.

Replacement of Glasses and Dentures

Executive councils have been told by the Ministry of Health that in replacing and repairing glasses "the criteria which are being applied in determining whether there has been carelessness are still not sufficiently exact." Claims should be admitted only when the ophthalmic services committee are satisfied beyond reasonable doubt that the loss or damage is due to circumstances beyond the applicant's control. Similar criteria should be applied when claims for replacement of dental appliances are considered. "Examination of some of the schedules of actual claims for denture replacement makes it apparent that a great many claims derive from the alleged loss of dentures in cases of vomiting. Claims of this kind have undoubtedly been much too readily accepted by some Executive Councils as justifiable." Where there has been lack of reasonable precaution or care, councils should normally require the patient to bear the entire cost of replacement, except when they are satisfied that this would involve substantial financial hardship.

Central Midwives Board

Mr. Arnold Walker has been re-elected chairman, and Dr. J. P. Hedley vice-chairman, of the board for the coming year.

Association of Sea and Air Port Health Authorities of the British Isles

This association is holding its annual meeting at Grimsby on June 7, 8, and 9. Further particulars may be had from Dr. H. C. Maurice Williams, health department, Civic Centre, Southampton.

Care of the Aged

A meeting to discuss medical aspects of the care of the aged will be held at the Hope Hospital, Salford, on Thursday, May 4, at 5 P.M. The speakers will include Dr. J. M. Greenwood, Dr. Marjory Warren, and Dr. E. B. Brooke, who will also take part in an informal conference on the coöperation of home and hospital in the care of the aged which will take place the following day at Salford Town Hall at 2.30 P.M.

Institute of Child Health

Prof. Ph. Sandblom, surgeon-in-chief to the Crown Princess Louise's Children's Hospital, Stockholm, will deliver the Alex Simpson-Smith lecture for 1950 at the Hospital for Sick Children, Great Ormond Street, London, W.C.1, on Thursday, May 25, at 5 P.M. He is to speak on Factors Influencing the Rate of Wound Healing. Tickets may be had from the director of the institute.

Blood Donations

Blood donors set up a new post-war record in 1949 by contributing over 456,000 bottles of blood to the National Blood Transfusion Service for hospitals in England and Wales. This was an increase of 72,000 on 1948 and of 160,000 on 1947. New donors totalled 133,000, compared with 98,000 and 72,000 in the two preceding years; but another 200,000 are needed to reinforce the 369,000 on donor panels at the end of the year.

Course in Tropical Hygiene for Planters and Miners

The annual course for laymen will be held by the Ross Institute this year from Monday, July 24 to Friday, July 28. The morning sessions will provide a continuous course on malaria and its control, and in the afternoons there will be lectures on other subjects, such as hookworm, bilharzia, nutrition, housing and sanitation, and protection against heat. There is no fee for the course, but those who wish to attend should send their names as soon as possible to the organising secretary of the institute, Keppel Street, London, W.C.1.

Liverpool Emergency Bed Bureau

During the three months from November, 1949, to January of this year, the Liverpool Emergency Bed Bureau dealt with 3516 cases. In 3151 of these it succeeded in admitting the patients, and in a further 168 accommodation was found which was not accepted. The bureau failed, in the first instance, to place 197 patients, but later arranged admission for 78 of these. Of the 197 "failures," 70 were children under 12 years of age (54 being under the age of 2 years) and 79 were over 60 years of age. For about ten days at the end of November and beginning of December accommodation for maternity cases was insufficient.

Too Many Residents?

At a meeting of the Sheffield Regional Hospital Board on April 17, Lord Quibell, chairman of Scunthorpe Hospital Management Committee, complained of the "wasteful overstaffing of hospitals with resident doctors." There were, he said, far too many registrars and house doctors; and the Ministry of Health should take action. Dr. W. A. Ramsay, senior administrative officer of the board, is reported by the *Daily Telegraph* (April 18) to have replied that the Ministry had asked regional boards to investigate the number of doctors employed in hospitals; and the boards were seeking detailed reports from the management committees. "There has been some difference of opinion between us and the committees, but generally we want to cut the numbers down and the committees want to keep them up." The number of people attending hospitals, said Dr. Ramsay, was now much greater, and it was difficult to justify a reduction; for if this were effected, then either hospital work would have to be reduced or the consultant staff would have to undertake more work.

Notes and News

EFFECTS OF MASS B.C.G. VACCINATION

MEASURING the effects of mass B.C.G. vaccination by the subsequent tuberculosis mortality involves long delay. This time-lag, Dr. T. Gedde-Dahl[1] suggests, might be overcome by studying the earliest manifestations of infection with tuberculosis. In Norway both erythema nodosum and pleurisy are notifiable; and since 1941 their incidence has declined remarkably, as the following figures show:

	Erythema nodosum	*Pleurisy*
1941	1374	2989
1942	1416	2687
1943	1155	2203
1944	1192	2293
1945	1073	2108
1946	1147	1991
1947	859	1708
1948	634	1217

It will be seen that the fall in numbers was greatest in the last two years, during which, for the first time, mass B.C.G. vaccination was carried out (about 35,000 vaccinations in 1947, and about 135,000 in 1948). There are, of course, various other factors for which credit can be claimed; during the past decade there have been large advances in the campaign against tuberculosis, and since 1943 mass radiography has played an important part. The invidious task of apportioning marks between all the factors capable of reducing morbidity and mortality would tax the ingenuity of any statistician, and Dr. Gedde-Dahl is not prepared to rush in where purists would not tread. But he has a suggestion to make: let tuberculosis notifications be accompanied by a statement that the person concerned has, or has not, been vaccinated with B.C.G. In countries where mass vaccination with B.C.G. is extensively practised, this plan might well yield valuable information.

ADDITIONS TO THE POISONS LIST

THE following changes are to be made in the poisons list and rules:

D. F. P. (*di-isopropyl fluorophosphonate*) will be added to part I of the poisons list and included in the first and seventh schedules to the poisons rules. The special labelling requirements prescribed by the seventh schedule will apply to eyedrops as well as to injection solutions.

Deca-, hexa-, penta-, &c., methonium iodide will be added to part I of the poisons list and included in the first and fourth schedules to the poisons rules. They will be listed as "polymethylene bis-trimethyl ammonium salts."

Anti-histamine drugs will be added to part I of the poisons list and included in the first and fourth schedules to the poisons rules. Exemption will be provided for preparations intended for external application only.

Synthetic drugs.—The following drugs to which part III of the Dangerous Drugs Act, 1920, is shortly to be applied will be added to part I of the poisons list and included in the first schedule to the poisons rules:

Alphaprodine (α-4-propionoxy-4-phenyl-1 : 3-dimethyl-4-piperidine) its salts;
Betaprodine (β-4-propionoxy-4-phenyl-1 : 3-dimethyl-4-piperidine) its salts;
Hydroxypethidine (ethyl-4-*m*-hydroxyphenyl-1-methylpiperidine-4-carboxylate) its salts;
Isoamidone (6-dimethylamino-4 : 4-diphenyl-5-methylhexan-3-one) its salts;
Ketobemidone (4-propionyl-4-*m*-hydroxyphenyl-1-methylpiperidine) its salts;
Methadol (6-dimethylamino-4 : 4-diphenylheptan-3-ol) its salts;
Methadyl acetate (6-dimethylamino-4 : 4-diphenyl-3-heptyl acetate) its salts.

Part III of the Dangerous Drugs Act, 1920, will also be applied to phenadoxone, a poison at present included in part I of the poisons list and in the first [illegible] under the description "[illegible]; its salts." The name [illegible] will be adopted in part I [illegible] to the poisons rules. The [illegible] leleted as no poison in that schedule is also subject to control under the Dangerous Drugs law.

The British and American conventional form will be adopted in the Dangerous Drugs law for amidone, a poison included in part I of the poisons list and the first schedule to the poisons rules. [illegible] ne) its [illegible] list and [illegible] amidone [illegible]

Rules 7 and 12 of the poisons rules will be amended to legalise the supply in ampoules of an additional quantity of a poison sufficient to permit the withdrawal and administration of the quantity ordered and the amount prescribed.

NUFFIELD TRUST IN NORTHERN IRELAND

THE first meeting took place recently in Belfast of the Northern Ireland committee of the Nuffield Provincial Hospitals Trust. In 1942 the Northern Ireland Regional Hospitals Council was constituted under the chairmanship of Mr. D. Lindsay Keir (now Sir David Lindsay Keir). This council was formed under the ægis of the Nuffield Provincial Hospitals Trust, and it will be remembered mainly for its "Survey of the Hospitals Services of Northern Ireland," published in 1945, and for its "Plan for the Hospital Services for Northern Ireland," published in 1946. With the passing of the Health Services Act (Northern Ireland), 1948, it was believed that the council had fulfilled its main purpose. It was felt, however, that there was a place for an independent voluntary body, fully representative of all the health and social services; and accordingly the council's final act was to draw up a new constitution, providing for the formation of a committee to be known as the Northern Ireland committee of the Nuffield Provincial Hospitals Trust.

Under its constitution this committee has for its aims: (*a*) to assist the coördination on an area basis of hospital services; (*b*) to initiate and promote research which aims at the raising of the standard of hospital services throughout the area; and (*c*) to advise on any proposals which serve the foregoing purposes. Further, its functions are to advise and coöperate with the statutory and other bodies on such matters as may seem conducive to the improvement of the hospital, ancillary, or auxiliary services within the area, and also to initiate, promote, and encourage, whether independently or in consultation with appropriate bodies, research on the causation, prevention, and treatment of disease, and for the improvement of the hospital, ancillary, and auxiliary services. It aims to achieve in every possible way the raising of the standard of service to the patient throughout the area.

"IN PRAISE OF NURSES"[1]

NURSES have always deserved a poet to sing their praises, and it is pleasant that they should have found such a distinguished one as Mr. John Masefield. In a set of verses he declares his appreciation, especially, of the five who lately nursed him in sickness:

> "All honour Doctors; let me honour those
> Who tend the patient when the doctor goes."

He wrote at that enchanted stage of recovery when every one of the five seemed more than human, more than the kind young woman his wits knew her to be; and this is surely the right moment to praise nurses for the essential quality of their art. To each other they may be sensible, jolly, hard-working, flippant, talkative, or a dozen other things that go with youth, hearty appetites, and simple tastes; but to the sick man they have something to give of which they are themselves unaware until they fall sick and experience it—a nourishing tenderness springing from their own strongest and most lasting instinct. It was this quality which another poet had in mind when he wrote:

> "When pain and anguish wring the brow
> A ministering angel thou."

—lines now so hackneyed that they can hardly be read without a smile. Mr. Masefield, less romantic and more direct about it, writes of them

> "*Cleansing the foul*, and smiling through the pique
> *Of nerves unstrung* . . ."

He ends with a gratitude and simplicity which we must all share on his behalf:

> "I thank and bless you: that I write at all
> Is, by itself, your work's memorial."

University of Cambridge

At a congregation to be held on June 8 the honorary degree of SC.D. will be conferred on Dr. William S. Middleton, dean of the medical school of the University of Wisconsin.

University of Birmingham

On May 15, 16, 17, and 18, at 4 P.M., Prof. Herbert M. Evans, director of the institute of experimental biology, University of California, will deliver the William Withering lectures at the anatomy theatre of the medical school. He is to speak on the Internal Secretions of the Anterior Lobe of the Pituitary Body.

STREPTOMYCIN IN ACUTE MILIARY TUBERCULOSIS

A REPORT TO THE MEDICAL RESEARCH COUNCIL

EARLY in 1947 a trial of streptomycin in the treatment of acute miliary tuberculosis was undertaken by the Streptomycin in Tuberculosis Trials Committee of the Medical Research Council.* At first it was proposed to admit cases to only three centres, but later other centres participated in the trial. The centres and the specialists in charge of patients and pathological work were:

Alder Hey Children's Hospital, Liverpool.—Clinician: Prof. N. B. CAPON. Pathologist: Prof. A. W. DOWNIE.

Brompton Hospital, London.—Clinician: Dr. W. E. LLOYD. Pathologists: Dr. J. W. CLEGG and Dr. D. A. MITCHISON.

Guy's Hospital, London.—Clinician: Dr. P. R. EVANS. Pathologist: Dr. F. L. JACKSON.

Hammersmith Hospital (Postgraduate Medical School of London).—Clinician: Dr. J. W. CROFTON. Pathologist: Dr. MARY BARBER.

Harefield Hospital, Middlesex.—Clinician: Dr. R. H. BRENT. Pathologist: Dr. E. NASSAU.

Highgate Hospital, London.—Clinician: Dr. J. RUBIE. Pathologists: Dr. J. M. ALSTON and Dr. A. MOHUN.

Hospital for Sick Children, Great Ormond Street, London.—Clinicians: the consultant staff, with Dr. P. M. RANSFORD as registrar. Pathologist: Dr. I. A. B. CATHIE.

St. Charles Hospital (L.C.C.), London.—Clinician: Dr. T. V. MENDELSOHN. Pathologist: Dr. MARY BARBER (Hammersmith).

Dr. Marc Daniels, of the council's Tuberculosis Research Unit, was responsible for the clinical coördination of the trial, and he also prepared the report for the committee. X-ray changes were assessed by an independent panel composed of Dr. L. G. Blair, Dr. Peter Kerley, and Dr. Geoffrey S. Todd.

As in other trials undertaken by the committee, the centres kept uniform records and followed recommendations made regarding dosage and duration of treatment. As in the trial in tuberculous meningitis (but not the trial in pulmonary tuberculosis) all patients were treated with streptomycin, since the very high fatality of acute miliary tuberculosis rendered a control series unnecessary. Moreover, preliminary results from the U.S.A. suggested that the drug is effective in this condition.

This report analyses the records of all the patients fulfilling the criteria given below and admitted for treatment under the scheme between March 22 and Sept. 30, 1947 (numbering 25). Though many reports on the subject have been published, this one should have particular value in virtue of the two-year follow-up of the survivors.

Diagnostic Criteria

Particulars and chest radiographs of all patients were submitted to a panel of clinicians. Cases were accepted if in the opinion of the panel (*a*) the X-ray appearances were consistent with a diagnosis of miliary tuberculosis, (*b*) there was additional definite or presumptive evidence that the origin was tuberculous, and (*c*) the condition was acute. Patients found on admission to have meningitis as well are excluded from this analysis.

Bacteriological Proof

Though bacteriological proof before the start of treatment was not required, in 14 of the 25 cases pre-treatment specimens were positive for tubercle bacilli—in 4 of these on sputum smear, and in the others by cultures of sputum (1), laryngeal swab (1), or gastric washings (8).

In 7 cases specimens taken on admission did not yield tubercle bacilli but later specimens were positive.

In 2 of these 7 cases tubercle bacilli were found one month after admission. In 1 the first isolation was from the cerebrospinal fluid (C.S.F.) when meningitis developed three and a half months after start of treatment. In 3 cases positive results were not obtained till much later—one nine months later from cavitating pulmonary lesions, one ten months later from pericardial fluid, and one thirteen months later when meningitis developed. In 1 case cultures from tissues at post-mortem examination were the first positive ones to be obtained.

In 4 cases tubercle bacilli were not isolated at any time.

Of these 4 patients, 2 died but no necropsy was performed: one died two days after admission; the other (case 15), a child of fourteen months, had a history of contact, a tuberculous hip and cervical adenitis, a primary complex in addition to the miliary lesions, and developed meningitis.

A boy of 5 (case 23) had a history of contact, and was tuberculin-positive. A month after admission, choroidal tubercles were seen, and later he developed meningitis. He also developed skin lesions which histologically had the appearance of tuberculides.

The fourth patient, aged 27, had a characteristic history and her X-ray film showed, in addition to typical miliary shadows, calcified lesions at both apices. She was acutely ill. The lesions cleared in the same length of time as in other patients who responded well.

Unfortunately tubercle bacilli were not sought systematically in the urine of all patients in this investigation.

Tuberculin Test

Of the 25 patients, 19 were given a complete Mantoux test and 18 reacted positively. The remaining patient tested, negative to Old Tuberculin 1 in 100 (case 5), was very acutely ill on admission; one month after start of treatment he too was tuberculin-positive.

Radiological Appearances

In 17 cases radiography showed the classical millet-seed dissemination with well-defined nodules 1–2 mm. in diameter. The other 8 patients presented larger (3–5 mm.) nodules, more fluffy in outline, but, as in the first group, evenly spread over both lungs.

Treatment

Streptomycin was given as the sulphate by the intramuscular route in daily doses of 2 grammes for persons aged fourteen or over, and of 20 mg. per lb. of body-weight (up to a dose not exceeding 2 g.) for those below that age. The daily dose was given in four injections at six-hourly intervals. Since the work embodied in this report was done, it has become a practice to give streptomycin at twelve-hourly intervals or in one daily injection. The treatment was given continuously for three months or more.

Results

On October, 1949 (i.e., between two and two and a half years after the beginning of treatment) the survivors of the original 25 patients numbered 14 (56%). Excluding 3 patients who died in the first week of treatment, the proportion of survivors is 64%. Fig. 1 shows the numbers and percentages of survivors at different periods after the start of treatment. At six months 72% of patients survived; at one year 60%; at two years 56%.

The figures in table I showing fatality in age-groups suggest that the prognosis is worst in children under two years of age, and best in older children; excluding the 3 who died in less than a week, the fatality in children aged two to fourteen was 15% (2 out of 13). The totals involved, however, are small and the differences are not statistically significant.

---

* Members: Dr. GEOFFREY MARSHALL (chairman), Prof. J. W. S. BLACKLOCK, Prof. C. CAMERON, Prof. N. B. CAPON, Prof. ROBERT CRUICKSHANK, Prof. J. H. GADDUM, Prof. F. R. G. HEAF, Prof. A. BRADFORD HILL, Dr. L. E. HOUGHTON, Dr. J. CLIFFORD HOYLE, Prof. H. RAISTRICK, Dr. J. G. SCADDING, Prof. W. H. TYTLER, Dr. G. S. WILSON, and Dr. P. D'ARCY HART (secretary).

Roffey Park Rehabilitation Centre

This centre has been removed from the St. Thomas's Hospital group.

World Health Assembly

The third World Health Assembly will open on Monday, May 8, at the Palais des Nations at Geneva.

British Association

The annual meeting of the association will be held this year in Birmingham from Aug. 30 to Sept. 6, under the presidency of Sir Harold Hartley.

Society for Psychical Research

Prof. J. B. Rhine, director of the parapsychology laboratory, Duke University, North Carolina, will deliver the Myers lecture at the Caxton Hall, Westminster, S.W.1, on Wednesday May 10, at 8.30 P.M. He is to speak on Telepathy and Human Personality.

Institute of Hospital Administrators

At 10.30 A.M. on Friday, May 5, Mr. Aneurin Bevan will open the two-day conference of this institute at Caxton Hall, Westminster, S.W.1. Further particulars may be had from the secretary of the institute, Tavistock House North, London, W.C.1.

Dr. W. S. C. Copeman is to attend the opening of a university department of rheumatism in Barcelona on May 10, and to deliver a short course of lectures.

CORRIGENDUM: *Research on Arthritis Treatment.*—In the procedure described by Dr. Landsberg in his letter of April 1 (p. 643), the strength of the aqueous methylene-blue solution of which 10 ml. was injected intramuscularly or intravenously was 10%.

Diary of the Week

APRIL 30 TO MAY 6

Monday, 1st

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.1
5 P.M. Prof. E. C. Dodds, F.R.S.: Recent Advances in Endocrinology in relation to Diagnosis and Treatment. (First of a course of lectures in General Medicine.)

TOWNLEY, J. C., M.R.C.S.: Cambridge.

Births, Marriages, and Deaths

BIRTHS

BROWNE.—On April 18, in London, the wife of Mr. Denis Browne, F.R.C.S.—a daughter.
DINNICK.—On April 21, in London, the wife of Dr. O. P. Dinnick—a son.
MCDOUGLE.—On April 21, at Norwich, the wife of Dr. H. A. McDougle—a son.
OLIVER.—On April 14, at Norwich, the wife of Dr. W. A. Oliver—a daughter.
WHITNEY.—On April 18, at Broseley, Salop, the wife of Dr. Rupert Whitney—a son.

MARRIAGES

GOLDSMITH—FITZGERALD.—On April 15, at Seaford, Kenneth Leslie Grant Goldsmith, M.B., to *Pamela Aileen* Fitzgerald, S.R.N.
KENDRICK—MENSCH.—On April 18, at Bolton, Lancs, Bernard Kendrick, M.B., to Katherine Mensch, B.A.

DEATHS

APPLETON.—On April 22, in London, Arthur Beeny Appleton, M.A., M.D. Camb.
BALFOUR.—On April 18, at Aviemore, Archibald Craig Balfour, L.R.C.P.E.
BEACH.—*On April 17, at* Weymouth, Henry William Beach, M.R.C.S., D.P.H., aged 78.
BOWDEN.—On April 19, at Boscombe, *Reginald* Trencher Bowden, M.D. Durh., aged 89.
DEEPING.—On April 20, George Warwick Deeping, M.A., M.B. Camb., aged 72.
HOLTHUSEN.—On April 20, Alan William Holthusen, M.B. Lond., aged 64.
HUTCHINSON.—On April 20, Roger Jackson Hutchinson, M.R.C.S.
JOSCELYNE.—On April 17, Arthur Edwin Joscelyne, M.D. Durh., aged 83.
LE QUESNE.—On April 14, at Bristol, *Ferdinand* Simeon Le Quesne, V.C., M.R.C.S., lieut.-colonel, R.A.M.C. retd., aged 86.
MANSON.—On April 17, David Manson, M.B. *Glasg.*, aged 66.
MARTIN.—On April 17, at Didsbury, Lancs, Ernest Martin, M.B. Durh.
O'HEA.—On April 17, at Croydon, James Patrick O'Hea, M.B. Lond., F.R.C.S., aged 82.
RODD.—On April 16, at Yelverton, South Devon, Arthur Rodd, M.R.C.S., captain, R.A.M.C. retd., aged 55.
STODDART.—In April, in London, William Henry Butter Stoddart, M.D. Lond., F.R.C.P.
WHITE.—On April 19, in London, Christopher *Theodore Redwood* White, L.R.C.P.E., aged 76.

in all respects. She weighed 28 lb. more than on her admission to hospital and was working as a shop assistant.

RECOVERY WITH RESIDUAL PULMONARY TUBERCULOSIS (1 CASE)

Case 25.—A girl of 11 had been ill for three months when admitted for treatment; her general condition was good but the temperature was between 98 and 101·6°F and the sedimentation-rate was 60. The radiological shadows were of the coarse nodular type. The temperature came down two days after starting treatment and clinically she improved considerably within the first weeks of treatment, though the temperature rose again and she did not become apyrexial again until twelve weeks after treatment started. Radiological clearing was first seen at the end of the second month and continued slowly subsequently. Though the miliary lesions were still visible at six months, clinically she seemed to have fully recovered, had a temperature within normal limits, had gained 12 lb. in weight, and her sedimentation-rate was 16. With the clearing of miliary shadows small lesions at both apices became apparent. She was transferred to a country tuberculosis hospital and her condition closely watched. Fourteen months after the start of treatment, tomograms showed cavities at the left apex. A pneumothorax was induced but later abandoned because of contraselective collapse. Following induction of a pneumoperitoneum she made good progress, and at the last examination, two years after first admission for miliary tuberculosis, she was in good general condition, afebrile, had a sedimentation-rate of 5 and negative sputum.

MENINGITIS (8 CASES)

In 8 cases the patient developed clinical tuberculous meningitis during or after the cessation of treatment. Of these 8, 7 had temperatures of 101°F or over on admission; case 21 was apyrexial and remained so even when meningitis developed. In case 22, C.S.F. findings during treatment were suggestive of meningitis, but the patient improved, only to develop clinical meningitis several months after treatment had stopped. Her case is described below with 3 other cases of meningitis arising after the end of treatment.

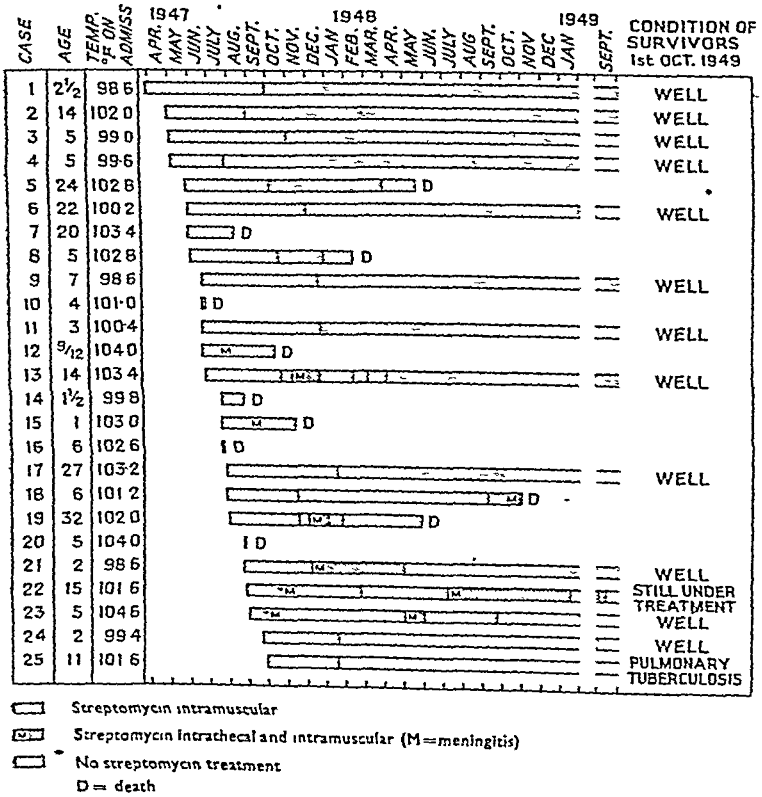

Fig. 2—Results in each of 25 patients whose treatment started between March and September, 1947.

Meningitis Developing during Treatment

Of the 4 patients in this group, 2 were infants under fifteen months, 1 was two years old, 1 was five years old. The 2 infants both died, the 2 older children have survived.

Both infants came from tuberculous families. One (case 12) had shown much clinical improvement after being desperately ill during the first week of treatment, but the C.S.F. at one month showed 30 cells per c.mm., protein 240 mg. per 100 ml., and chlorides 680 mg. Pyrexia persisted, but otherwise clinical improvement was maintained until the fourth month, when he was found one morning semicomatose and with right hemiplegia. He died four days later. Radiologically there had never been any clearing, and post-mortem examination showed widespread miliary lesions with meningitis. The other infant (case 15) had a tuberculous hip; he also improved clinically during the first months, but he developed meningitis towards the end of the second month, and died two months later. Neither of these patients had intrathecal treatment (at the time the value of intrathecal treatment had not been fully established).

Of the 2 children who have survived, 1 (case 21) developed meningitis in the fourth month of treatment. When admitted she was an ill child of two, with a sedimentation-rate of 44 but temperature within normal limits. The C.S.F. was normal, the Mantoux reaction was positive. Radiography showed disseminated coarse nodules in both lungs, collapse and consolidation of the left lower lobe, and an enlarged paratracheal gland. During the first three months after the start of treatment her general condition improved steadily; she gained weight and the sedimentation-rate fell to 19. Radiological clearing began at the end of two months. Three and a half months after the start of treatment she became irritable and ill generally; a clinical diagnosis of meningitis was confirmed by a characteristic C.S.F. picture, by the finding of choroidal tubercles, and by the culture of tubercle bacilli from the C.S.F. Intrathecal streptomycin was added to the intramuscular treatment and this was continued for four and a half months. She responded very well to the combined treatment. During this time the pulmonary lesions continued to clear. At nine months the C.S.F. was nearly normal and at twelve months she was discharged home, in good general condition and with a normal C.S.F. She has attended a chest clinic regularly since then and clinical improvement has continued uninterrupted.

Case 23.—The other surviving child who developed meningitis during treatment had an abnormal C.S.F. from the end of the first month of treatment. A boy of 5, with a history of one week, he was clinically acutely ill when admitted; his temperature ranged from 101 to 104·6°F, the E.S.R. was 35, and the chest X-ray film showed typical fine miliary dissemination. The C.S.F. was normal. His general condition improved in the first two months of treatment, though he remained febrile. One month after treatment started several choroidal tubercles were seen, and the C.S.F. was abnormal with 10 lymphocytes per c.mm., protein 150 mg. per 100 ml., and chlorides 700 mg. There were no clinical signs of meningitis, and no intrathecal treatment was given. At two months the clinical condition was still improving, and radiography showed some clearing of the miliary lesions; but the C.S.F. was abnormal as before. At three months there was slight clinical deterioration, the temperature was still high, choroidal tubercles were still present, and there was blurring of the disc margins; the protein and lymphocytes in the C.S.F. had increased. At this time a papular rash developed on the soles and palms; it persisted for several months, and was found to have histologically the character of tuberculides. After the temporary clinical setback at three months, he again improved and at six months

Although every case was considered acute on acceptance, 3 patients were apyrexial during the week after admission. It is obvious from table II that even with streptomycin treatment, the prognosis is still very grave in those most acutely ill on admission. There were 10 deaths among the 16 patients with temperatures of 101°F or over, compared with 1 death among the 9 others. Of the 12 patients who were considered clinically extremely ill, 9 died, as against 2 of the 13 less ill.

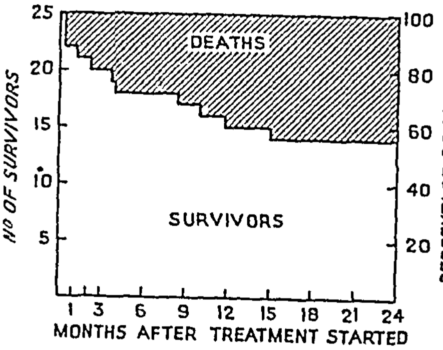

Fig. 1—Survivors at different periods after start of streptomycin treatment for miliary tuberculosis.

Similarly, 3 deaths occurred among 12 patients with sedimentation-rates (Westergren, 200 mm. reading at one hour) below 50, and 3 among 6 patients with rates over 50. In 7 cases the examination was not done.

Apart from primary complexes, 6 patients had manifest tuberculous lesions in addition to the miliary lesions seen on radiography. There were 3 deaths among them, and little difference in fatality is apparent between these 6 patients and those without any clinical evidence of other lesions (8 deaths among 19).

Radiological Progress of Miliary Lesions

The most remarkable feature of the response to treatment was the clearing of the miliary lesions in the lungs —not only in those patients who made a complete clinical recovery, but also in those who later died of meningitis or other complications. Of the 21 patients who survived more than two months, only 2 showed no radiological improvement; these were patients who died two and a half and three and a half months after treatment started.

TABLE I—RESULTS RELATED TO AGE

Age in years	Total	Died
Under 2	3	3
2–4	5	1*
5–9	8	4†
10–14	3	0
15 + ...	6	3

* Died in less than a week.
† Two died in less than a week.

Of the remaining 19, by two months clearing had commenced in 12, but in only 2 of these had improvement started in the first month (table III). In 4 cases radiological improvement was not seen until the third month, and in the remaining 3 it was not seen until the fourth.

The date at which the clearing of the miliary lesions in the lungs was first noted to be complete varied between four and eleven months after treatment started (table III); clearing took place in 17 out of the 18 patients who survived more than four months. The 1 exception was case 19 (death at ten months).

TABLE II—RESULTS RELATED TO ACUTENESS OF CONDITION ON ADMISSION

Cases	Temperature on admission (°F)				General condition on admission	
	102 +	101–101·9	99–100·9	Less than 99	Very ill	Others
Total	12	4	6	3	12	13
Deaths	8	2	1	0	9	2

Among the 17 patients whose X-ray films showed the typical millet-seed dissemination there were 8 deaths. Of the 8 patients who had the coarser nodule type, 3 died, 2 of them after clearing and then developing the classical miliary picture (cases 8 and 18, described later). On these small numbers no difference in fatality is apparent.

Clinical Course of the Disease (fig. 2)

As already stated, 3 extremely ill patients died after less than a week's treatment; 2 died within two days, while a 3rd child developed mediastinal emphysema on the fourth day and died on the sixth day. Of the remaining 22 patients, all but 1 (case 14) showed initial improvement. The clinical response of miliary tuberculosis to streptomycin is sometimes dramatic, with a fall in temperature and return of well-being within the first weeks; the sedimentation-rate falls more slowly. Frequently, however, the fever persists much longer, though at a level lower than at the start of treatment, and despite general improvement it may be many months before the clinical picture is wholly satisfactory. The prognostic importance of the early response to treatment is studied in the following analysis of the clinical course.

TABLE III—DATE OF RADIOLOGICAL CLEARING OF MILIARY LESIONS

Months after treatment started	1	2	3	4	5	6	7	8	9	10	11
Improvement first noted	2	10	4	3	..	..	..	..	..	..	..
Complete clearing ..	..	..	..	3	2	4	1	5	..	1	1

Of the 22 patients who survived more than a week, 9 recovered without complications, 1 recovered from miliary tuberculosis but with cavitating pulmonary lesions, 8 developed meningitis (4 died), and 4 died without meningitis.

UNINTERRUPTED RECOVERY (9 CASES)

Of the 9 patients who made an uninterrupted recovery 2 were apyrexial on admission but had a raised sedimentation-rate (43 and 47), and the rate did not return to normal till eight or nine months later. Of the 7 others, 5 had normal temperatures at the end of two months, and the remaining 2 at the end of four months. Case 2 is typical of this group of patients.

Case 2.—A girl of 14 had been ill for three months and her condition was diagnosed a month after her illness started. Her brother died of tuberculous meningitis during this time. On her admission to the centre for streptomycin treatment, she looked ill, had a temperature between 98·4 and 102°F, and a sedimentation-rate of 106. She had typical fine miliary infiltration of the lungs, enlarged hilar glands, and a probable primary focus in the left upper zone. She improved considerably within the first two weeks after treatment started; the temperature fell almost to normal by the ninth day but rose again to 101°F, and after that subsided gradually and remained normal from six weeks after start of treatment. There was a slow clinical improvement after the first two weeks and until the end of the fourth month; she gained a few pounds in weight and the sedimentation-rate fell to 55. Clearing of the miliary lesions began at four months and was amost complete at eight months, but the primary lesion at the left apex seemed little affected by treatment and in the fifth month a gland at the right hilum became enlarged and she developed collapse of the right dorsal lobe. At the end of the fourth month there was a slight setback; she had nausea and seemed lethargic. The C.S.F. was normal. Treatment was stopped and she then made considerable improvement clinically and gained weight rapidly. After a period of convalescence in a country hospital she was discharged home, and when last seen, over two years after treatment was first started, she was in excellent health in all respects. She weighed 28 lb. more than on her admission to hospital and was working as a shop assistant.

RECOVERY WITH RESIDUAL PULMONARY TUBERCULOSIS (1 CASE)

Case 25.—A girl of 11 had been ill for three months when admitted for treatment; her general condition was good but the temperature was between 98 and 101·6°F and the sedimentation-rate was 60. The radiological shadows were of the coarse nodular type. The temperature came down two days after starting treatment and clinically she improved considerably within the first weeks of treatment, though the temperature rose again and she did not become apyrexial again until twelve weeks after treatment started. Radiological clearing was first seen at the end of the second month and continued slowly subsequently. Though the miliary lesions were still visible at six months, clinically she seemed to have fully recovered, had a temperature within normal limits, had gained 12 lb. in weight, and her sedimentation-rate was 16. With the clearing of miliary shadows small lesions at both apices became apparent. She was transferred to a country tuberculosis hospital and her condition closely watched. Fourteen months after the start of treatment, tomograms showed cavities at the left apex. A pneumothorax was induced but later abandoned because of contraselective collapse. Following induction of a pneumoperitoneum she made good progress, and at the last examination, two years after first admission for miliary tuberculosis, she was in good general condition, afebrile, had a sedimentation-rate of 5 and negative sputum.

MENINGITIS (8 CASES)

In 8 cases the patient developed clinical tuberculous meningitis during or after the cessation of treatment. Of these 8, 7 had temperatures of 101°F or over on admission; case 21 was apyrexial and remained so even when meningitis developed. In case 22, C.S.F. findings during treatment were suggestive of meningitis, but the patient improved, only to develop clinical meningitis several months after treatment had stopped. Her case is described below with 3 other cases of meningitis arising after the end of treatment.

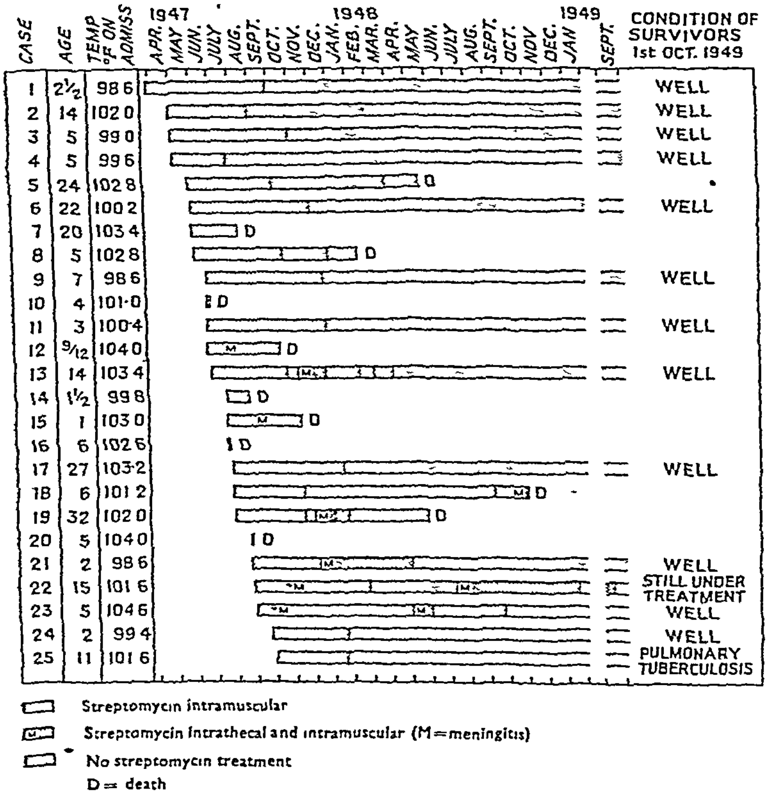

Fig. 2—Results in each of 25 patients whose treatment started between March and September, 1947.

Meningitis Developing during Treatment

Of the 4 patients in this group, 2 were infants under fifteen months, 1 was two years old, 1 was five years old. The 2 infants both died, the 2 older children have survived.

Both infants came from tuberculous families. One (case 12) had shown much clinical improvement after being desperately ill during the first week of treatment, but the C.S.F. at one month showed 30 cells per c.mm., protein 240 mg. per 100 ml., and chlorides 680 mg. *Pyrexia persisted*, but otherwise clinical improvement was maintained until the fourth month, when he was found one morning semicomatose and with right hemiplegia. He died four days later. Radiologically there had never been any clearing, and post-mortem examination showed widespread miliary lesions with meningitis. The other infant (case 15) had a tuberculous hip; he also improved clinically during the first months, but he developed meningitis towards the end of the second month, and died two months later. Neither of these patients had intrathecal treatment (at the time the value of intrathecal treatment had not been fully established).

Of the 2 children who have survived, 1 (case 21) developed meningitis in the fourth month of treatment. When admitted she was an ill child of two, with a sedimentation-rate of 44 but temperature within normal limits. The C.S.F. was normal, the Mantoux reaction was positive. Radiography showed disseminated coarse nodules in both lungs, collapse and consolidation of the left lower lobe, and an enlarged paratracheal gland. During the first three months after the start of treatment her general condition improved steadily; she gained weight and the sedimentation-rate fell to 19. Radiological clearing began at the end of two months. Three and a half months after the start of treatment she became irritable and ill generally; a clinical diagnosis of meningitis was confirmed by a characteristic C.S.F. picture, by the finding of choroidal tubercles, and by the culture of tubercle bacilli from the C.S.F. Intrathecal streptomycin was added to the intramuscular treatment and this was continued for four and a half months. She responded very well to the combined treatment. During this time the pulmonary lesions continued to clear. At nine months the C.S.F. was nearly normal and at twelve months she was discharged home, in good general condition and with a normal C.S.F. She has attended a chest clinic regularly since then and clinical improvement has continued uninterrupted.

Case 23.—The other surviving child who developed meningitis during treatment had an abnormal C.S.F. from the end of the first month of treatment. A boy of 5, with a history of one week, he was clinically acutely ill when admitted; his temperature ranged from 101 to 104·6°F, the E.S.R. was 35, and the chest X-ray film showed typical fine miliary dissemination. The C.S.F. was normal. His general condition improved in the first two months of treatment, though he remained febrile. One month after treatment started several choroidal tubercles were seen, and the C.S.F. was abnormal with 10 lymphocytes per c.mm., protein 150 mg. per 100 ml., and chlorides 700 mg. There were no clinical signs of meningitis, and no intrathecal treatment was given. At two months the clinical condition was still improving, and radiography showed some clearing of the miliary lesions; but the C.S.F. was abnormal as before. At three months there was slight clinical deterioration, the temperature was still high, choroidal tubercles were still present, and there was blurring of the disc margins; the protein and lymphocytes in the C.S.F. had increased. At this time a papular rash developed on the soles and palms; it persisted for several months, and was found to have histologically the character of tuberculides. After the temporary clinical setback at three months, he again improved and at six months was very lively, and the X-ray film was clear; but he was still febrile, and the C.S.F. was still abnormal. At eight months there was again a clinical setback, and it was finally decided to add intrathecal streptomycin to the intramuscular treatment which had been given continuously. The intrathecal treatment was given for one month, and the intramuscular treatment until the end of thirteen months after admission. He responded well, and the subsequent history is one of steady clinical improvement. The tuberculides and choroidal tubercles healed, the C.S.F. was normal at twelve months. A low pyrexia persisted for a long time, and he was not finally discharged from hospital until twenty months after admission. He has since attended regularly for check-up and has continued to make good progress.

Meningitis Developing after Treatment

The ages of the 4 patients in this group were 6, 14, 15, and 32 years, whereas all 4 patients who developed meningitis during treatment were under 6. There were 2 deaths. In 2 cases (13 and 19) meningitis developed two weeks after the end of treatment.

Case 13.—A girl of 14 showed little clinical response during the first two months of treatment; she remained pyrexial and lost weight, and at the end of two months choroidal tubercles were seen. In the fourth month there was marked clinical improvement, with temperature fall and considerable radiological clearing. At the end of four months she appeared very well, though still with a slight evening pyrexia; treatment was stopped, but two weeks later the temperature rose again, and the girl was again ill, with headache and vomiting; there were clinical signs of meningitis, a fresh crop of choroidal tubercles and a C.S.F. characteristic of tuberculous meningitis. She was given intrathecal and intramuscular streptomycin, and responded well. Strains of bacilli isolated from the C.S.F. at four and a half months, and from the urine at six months, were streptomycin-sensitive. Subsequently she made a complete recovery: when last seen, two years after first admission, she was clinically well in all respects.

Case 19.—A woman of 32 was admitted very ill, with a history of several months since the birth of a child. In addition to dense miliary infiltration, there was cavitation in both upper zones, and a small effusion at the right base. The C.S.F. was normal. Clinically she improved rapidly in the first months of treatment; in the fourth month some radiological clearing was seen for the first time; the E.S.R. was 12, and she still had a low pyrexia. Treatment was stopped at three and a half months, but two weeks later she developed clinical meningitis. She appeared at first to respond well to intrathecal treatment, and radiologically there was further improvement, but the C.S.F. remained very abnormal; at eight months she began to go downhill and she died two months later. Moderately resistant strains had been isolated from the sputum at two months; at four months the first strain isolated from the C.S.F. was sensitive, but subsequent strains six weeks and four and a half months later were moderately resistant.

The other 2 patients relapsed with meningitis a considerable time after treatment had stopped—over four months in one case, ten months in another.

Case 22.—A girl of 15 was extremely ill on admission. She responded clinically to treatment, but after one month complained of headache, and the C.S.F. showed 100 cells (45 lymphocytes) per c.mm., and protein 100 mg. per 100 ml. She appeared subsequently to improve, however, apart from onset of total deafness. At the end of four months the lung fields were practically clear; she then still had a temperature between 98 and 101°F, and at the end of six months there was still a low pyrexia. The C.S.F. at six months was normal apart from a protein level of 105 mg. Treatment, which had been by the intramuscular route only, was then stopped, and at eight months she was discharged home, clinically well apart from total deafness and a C.S.F. protein at 75 mg. During the next three months she seemed to keep well, and put on weight; but she then developed fever, headache, and vomiting, and was admitted to hospital with tuberculous meningitis. The subsequent history is one of first response to intrathecal and intramuscular streptomycin for six months, a relapse two and a half months after this course stopped, and good response to a second course of treatment. At the time of reporting, two years and four months after she was first admitted for miliary tuberculosis, she was still in hospital, and still having streptomycin treatment by the intramuscular route. Her general condition was excellent, and she suffered from no disability except the persistent deafness. The last examination of the C.S.F. showed 6 cells per c.mm., protein 40 mg. per 100 ml., sugar 53 mg., and chlorides 720 mg.

Case 18.—A boy of 6½ had radiological shadows of the coarse nodular type. The condition had developed in hospital, where he was under observation with erythema nodosum. The response to the three and a half months' course of intramuscular streptomycin was good; at four months he still had a mild evening pyrexia, but was otherwise clinically well, had put on 12 lb. in weight, and had a normal lung picture. The low pyrexia persisted for several months, though in all other respects he was doing very well. Thirteen and a half months after his first admission, he was readmitted to hospital, not acutely ill, but with increased pyrexia, and general malaise. Radiography showed a typical dense millet-seed dissemination throughout both lungs. The C.S.F. was normal. Intramuscular streptomycin treatment was started again. Five weeks later choroidal tubercles were seen, and the C.S.F. then showed increased cells and a low sugar level, though there were no clinical signs of meningitis. Intrathecal treatment was started five days later, but he rapidly became worse and died ten days after the commencement of this treatment. Strains isolated from gastric washings on his readmission and from the C.S.F. when he developed meningitis were sensitive, but those from the C.S.F. on the day before his death and from a post-mortem specimen were highly resistant.

Choroidal Tubercles

Results of ophthalmoscopic examination were not recorded with sufficient constancy to permit an adequate analysis. However, there is no record of choroidal tubercles having been seen in any of these cases on admission; it must be remembered that patients with meningitis on admission were excluded.

Choroidal tubercles were observed later in 5 patients, and in all 5 the observation preceded or accompanied onset of tuberculous meningitis. In case 13 they were seen two months after treatment started; no lumbar puncture was done at the time, but the patient developed clinical meningitis two and a half months later. In 2 other cases (15 and 23) tubercles were seen at a time when there was no clinical meningitis but the C.S.F. was abnormal and suggestive of meningitis. In the 2 remaining cases (18 and 21), the observation was made when onset of clinical meningitis was apparent.

Debré et al. (1948), reporting results in 16 cases of miliary tuberculosis, record that choroidal tubercles were seen in 5 of the 6 patients who developed meningitis, and in only 2 of the others who did not. Bernard et al. (1949) found choroidal tubercles in 19 of 38 patients who developed meningitis, and in 13 of 56 who did not.

DEATH WITHOUT MENINGITIS (4 CASES)

All 4 patients were acutely ill on admission. A child of eighteen months (case 14), deteriorated progressively to his death five weeks later; at necropsy there was no meningitis, but very widespread miliary lesions and a large primary complex. Another patient (case 7), a girl of 20, had on admission, besides the typical fine miliary lesions in the lungs, a cervical abscess and tuberculous laryngitis. She improved slightly in the first two months, but there was no radiological clearing; her clinical condition then suddenly deteriorated and she died two and a half months after admission. Necropsy revealed very extensive large caseous lesions in many organs.

The two other cases are of particular interest.

Case 5.—An Indian, aged 24, had been ill for a month before admission with pyrexia of unknown origin, and repeated chest X-ray films were normal till a few days before admission to the centre, when the typical appearance of miliary tuberculosis was found. He was desperately ill on admission, and was in fact considered moribund. There was a remarkable response to treatment; clinically after the first dramatic improvement he made continuous further progress, and by the end of the third month he was apyrexial; radiological clearing began in the second month, and was complete at seven months. Treatment was stopped at four months; a week later he developed jaundice, but recovered from this without incident, as also from a small right spontaneous pneumothorax. He was discharged for convalescence at nine months, apyrexial, very fit, having gained over 40 lb. since admission. Three weeks later he was readmitted, acutely ill, with fever, extreme weakness, and precordial pain. He was found to have a pericardial effusion, and tubercle bacilli were grown from the fluid (the first and only to be isolated from this patient). The lungs remained clear. The condition did not respond to streptomycin given systemically and into the pericardial cavity, and he died, nearly a year after his first admission. Permission for post-mortem examination was refused.

Case 8.—A boy of 5 was acutely ill on admission with a temperature 99–102·8°F, and E.S.R. 60, and had radiologically disseminated shadows of the coarse nodular type. During the first month of treatment his condition became worse, but in the following months he improved progressively, though he retained a low pyrexia for many months. Radiological clearing was first seen in the third month, and was almost complete at the end of the fourth month. C.S.F. examinations during this period showed no abnormality. Treatment was stopped at four and a half months, and at five and a half months he was discharged home. Four weeks after his discharge, he was seen at outpatients, and appeared very fit, and the chest X-ray film was considered clear; but the E.S.R. was 19. A week later he developed acute tonsillitis and cervical adenitis, and after ten days (seven months after his first admission) was readmitted to hospital, ill, listless, with a high swinging temperature. Radiography showed a characteristic fine millet-seed dissemination in both lungs. Looking back through the films, the miliary shadows can be perhaps seen on the film at two months, definitely on the six-month film. Streptomycin treatment was given again, but the condition this time did not respond, and the child died seven weeks after his readmission. Miliary lesions were found in many organs, and large tuberculous abscesses in cervical and mesenteric glands. Tubercle bacilli isolated from these lesions were resistant. Histologically, the lungs and other organs contained both healing and active lesions.

The special interest of this case, as of case 18, is the character of the relapse, with a typical fine miliary picture appearing some time after treatment had cleared coarse nodular shadows.

Streptomycin Sensitivity

There were 4 deaths within the first six weeks. From 12 other patients tubercle bacilli were not isolated after the first six weeks. Of the remaining 9 cases, sensitivity tests were not done in 2 cases. Table IV relates therefore to only 7 cases.

Strains were isolated from the sputum of 3 patients; one was highly resistant at six weeks, and another moderately resistant at eight weeks and twenty-eight weeks (both these patients died); the third was sensitive at thirty weeks, and this patient recovered. A resistant culture was isolated at thirty-six weeks from the cervical glands of another patient who died. Strains from the gastric washings of one patient at fifty-six weeks were sensitive.

TABLE IV—STREPTOMYCIN SENSITIVITY. (The figures in parentheses are weeks after treatment started.)

Case	Specimen	Streptomycin sensitivity*	Clinical note
7	Sputum	1000(6) 1000(10)	Death (11)
8	Cervical gland	66(36)	Death (36)
13	Sputum Urine C.S.F.	0·5(30) 0·5(26) 0·5(18)	Meningitis (18) Recovered
18	Gastric washings C.S.F.	0·5(56) 0·5(61) 250(63)	Meningitis (61) Death (63)
19	Sputum C.S.F.	8(8) 12·5(28) 0·6(17) 12·5(23) 12·5(35)	Meningitis (17) Death (43)
21	C.S.F.	0·5(15)	Meningitis (15) Recovered
22	C.S.F.	0·5(48)	Meningitis (48) Recovered

* Reported as minimum concentration of streptomycin, in µg. per ml., to which tubercle bacilli were sensitive. The 'Tween'-albumin medium was used.

Strains isolated from the C.S.F. of 5 patients were all sensitive at the onset of meningitis (fifteen weeks, seventeen weeks, eighteen weeks, eleven months, and fourteen months after the start of treatment); in 1 case (19) a moderately resistant strain had been isolated from the sputum nine weeks previously. Of those cases which yielded further positive C.S.F. cultures, one had a moderately resistant strain (case 19) and another a highly resistant strain (case 18); a strange feature of this second case is that resistance emerged after only ten days' intrathecal treatment.

No conclusion is possible, since there is scanty evidence from 7 cases only. It is noteworthy however that sensitive strains were isolated from the C.S.F. after quite long periods of treatment by the intramuscular route. McDermott et al. (1947) record 2 cases in which "the strains first isolated from the C.S.F. were drug sensitive even though organisms from the corresponding systemic infections were highly resistant to streptomycin in vitro." They note also the appearance of in vitro resistance in 3 cases in which the organisms persisted in the fluid. In a case reported by Lincoln and Kirmse (1950), relapse with meningitis occurred twenty-five days after completing six months of treatment for miliary tuberculosis; the organisms then cultured from the C.S.F. were fully sensitive to streptomycin, but during the second month of treatment for meningitis strains were isolated which were highly resistant to streptomycin.

Other Reported Results

Comparison of the results of this investigation with those of investigations reported elsewhere is difficult, because of differences in methods of reporting and in

duration of observation, and sometimes also because of the inclusion of cases with meningitis at the start of treatment. However the main results reported to date are listed in table v.

Discussion

Though in this investigation the number of cases of miliary tuberculosis treated with streptomycin and followed up for two years or more is small, the analysis has revealed certain interesting features.

The effect of streptomycin in this form of the disease is striking; as has been observed already by many workers, the fatality has been reduced to below 50%. It is important to note, however, that the prognosis is much less favourable for those patients most acutely ill at the start of treatment. Of the 16 patients whose temperature was 101°F or higher at the start of treatment, 3 died within a week, and 7 died later. The miliary picture of the lungs is only a part of the picture of blood dissemination, and streptomycin seems to have relatively little effect where that dissemination is acute and massive by nature either of the patient's low resistance or of the lesions liberating tubercle bacilli into the circulation. This is reflected particularly in the figures for meningitis: 7 of the 16 patients with a temperature of 101°F or over at the start of treatment developed meningitis later, and only 1 of the 9 with lower temperatures. Thus the acuteness of the clinical state at the start of treatment is a fundamental factor in prognosis.

The rate of response to treatment is also important. Of the 21 patients who survived more than two months, 7 had normal temperatures at two months and all 7 survived, whereas 7 of 14 patients still pyrexial died. At four months after the start of treatment, of the 18 survivors 12 had normal temperatures and 1 of these died; of the 6 who were still pyrexial, 3 died later, and 3 others all developed meningitis but recovered. While the importance of the temperature response to treatment is demonstrated, it is equally evident that the clearing of miliary lesions in the lungs is no guide to prognosis; clearing had been seen in 6 of the 8 patients who developed meningitis, and in 2 patients who later died without meningitis. The miliary lesions in the lungs appear to be more accessible to the drug's action than the lesions in other parts of the body.

Meningitis is the main complication obscuring the prognosis, and, if it is to be cured by the addition of intrathecal treatment, it must be diagnosed as early as possible. The analysis has shown how often it supervenes in very acute cases, and in cases where temperature does not return to normal within the first months of streptomycin treatment; certainly in such cases one must be particularly alert to this risk. The onset may be very insidious, and early clinical diagnosis is difficult, even in patients under close hospital observation. It is important to examine the fundi frequently; discovery of choroidal tubercles is a danger signal, though they may be seen without meningitis. The only certain method of diagnosing meningitis early in cases of miliary tuberculosis is by examination of the C.S.F., made before the start of treatment and repeated the more frequently the more acute the condition and the less responsive to treatment. Minor changes in the elements of the C.S.F. may be difficult to interpret, but in this series every patient who showed some abnormality of the C.S.F. developed meningitis. It is reasonable to recommend introduction of intrathecal therapy where there is any doubt.

Emergence of streptomycin-resistant strains was observed in 4 of the 7 patients whose bacilli isolated after the first six weeks were tested for sensitivity. All 4 patients died, and the other 3 recovered. Most recent information indicates that emergence of streptomycin resistance may be prevented or delayed by giving the drug with *p*-aminosalicylic acid (Medical Research Council 1949, Veterans Administration 1949).

How long should treatment continue? In 4 cases meningitis developed after treatment had stopped; 2 of them had been treated by the intramuscular route for three and a half months, 1 for four months, 1 for six months. Another 2 patients died without meningitis some time after the cessation of treatment; they had been treated for four and four and a half months. No definite decision had been taken regarding duration of treatment for patients in this investigation, apart from the recommendation that all should have at least three months' continuous streptomycin therapy. Of the 18 patients who survived more than six months, 9 had been treated continuously in the first place for twelve to twenty-two weeks, 9 for six months or more. A post-hoc analysis of the results in these two groups is not strictly valid, since many reasons intervened in the decision to prolong treatment, but the fact that the 9 who were treated for six months or more all survived, while 4 of the 9 others died, is suggestive. Several authors have shown the frequency of meningitis or miliary relapse occurring within a few weeks after stopping treatment (Mattei 1947, Bunn 1948, Bernard et al. 1949). There is a growing impression that chemotherapy should be continued in all cases of miliary tuberculosis for at least six months, and possibly longer. This recommendation is most strongly to be made for those patients most acutely ill on admission, and for those who do not respond fairly rapidly to treatment. Possibly treatment after the six months should be continued with some other tuberculostatic drug.

Summary

In 25 cases, acute miliary tuberculosis was treated with streptomycin. The survivors, numbering 14 (56%), have been followed up for over two years.

Apart from the 3 patients who died in less than a week, all but 1 showed clinical response to treatment. Uninterrupted recovery took place in 9; 1 recovered from miliary disease but with residual pulmonary tuberculosis; 8 developed meningitis, and 4 of these died; 4 died without meningitis.

The miliary lesions in the lungs cleared in 19 of the 21 patients who survived more than two months.

The prognosis was much worse in the patients most acutely ill at the start of treatment than in the others: 10 of the 11 deaths, and 7 of the 8 cases of meningitis, occurred among the 16 patients with temperatures of 101°F or over at the start of treatment.

Early diagnosis of meningitis and the conduct of treatment are discussed.

The opinions expressed in this report represent a consensus of the opinions of the clinicians and pathologists engaged in the trial. The committee is greatly indebted to them for their constant coöperation. Particular thanks are due also to the nursing staff and laboratory technicians of the centres.

Addendum.—In April, 1950, all the 14 survivors had been observed for over two and a half years. Of the 2 patients still under treatment in October, 1949, case 25 still had a pneumoperitoneum and was making good progress; case 22 was discharged from hospital in December, 1949, and when last seen at outpatients in March, 1950, was in excellent health. The other 12 patients were well.

SURGERY IN PARKINSON'S DISEASE

COMPLETE SECTION OF THE LATERAL COLUMN OF THE SPINAL CORD FOR TREMOR

Leslie C. Oliver
F.R.C.S.
NEUROSURGEON, WEST END HOSPITAL FOR NERVOUS DISEASES, AND ROYAL NORTHERN HOSPITAL, LONDON; SURGEON IN CHARGE OF NEUROSURGICAL CENTRE, OLDCHURCH HOSPITAL ROMFORD

Experience gained from 79 cordotomies done for the relief of parkinsonian tremor has shown that satisfactory results can be obtained only if patients are chosen for operation with the greatest possible care, and that the maximum elimination of tremor, without permanent paralysis, occurs after a complete section of the lateral column of the spinal cord at the second cervical segment. Ebin[1] claims good results in 11 patients from division of the lateral pyramidal and the opposite ventral pyramidal tracts through a single incision in the cord at the fifth cervical segment (3 in figure).

I have previously described[2] the effects of a 5 mm. cut into the posterior part of the lateral column (2 in figure) and drew attention to the observation that the results were better in those patients who, after operation, had patches of analgesia on the opposite side, from involvement of the lateral spinothalamic tract. In an attempt to improve the results still further I increased the extent of the incision in the cord to include the whole of the lateral column (4 in figure), so that complete analgesia was produced on the opposite side to a level high up on the thorax and sometimes including the upper limb.

SELECTION OF PATIENTS FOR OPERATION

With rare exceptions, patients with bilateral parkinsonism are unsuitable for cordotomy because, though the tremor is often severe, the major symptom is loss of dexterity, sometimes amounting to complete helplessness. Even more important is the fact that the patient's mental state is usually incompatible with a good result. It is possible to relieve tremor, but it is another matter to satisfy the patient. The problem is similar in some respects to the surgical treatment of intractable pain. The surgeon must be convinced that the patient will be grateful for his efforts. I have records of patients who have come to me with the most violent tremor and have been "bitterly disappointed" after operation because they have had a little tremor occasionally when excited. On the other hand, others have been happy with a moderate reduction of tremor after the more conservative operation.

Patients selected for complete division of the lateral column should have the disease confined strictly to one side, and it is important to note that a patient with tremor on one side is not necessarily suffering from unilateral disease, for there may be mental changes, a bilateral masking of the face, and some rigidity of the opposite side to reveal that both sides are affected. The radical operation, the subject of this article, is not advised if there is the slightest evidence of bilateral disease, partly for the reasons already mentioned and also because it is unjustifiable to leave a patient with bilateral analgesia.

A strictly unilateral syndrome is diagnosed after careful investigation. A history from relations should reveal no unfavourable mental changes. There should be masking of one side of the face only. When the patient walks, the unaffected arm should swing freely and there should be no suspicion of disability or rigidity on this side.

Even when it is decided that the parkinsonism is confined to one side, the patient as well as his malady must be carefully studied. If the tremor is the presenting symptom, the surgeon must discover what part it plays in the patient's life as well as its importance in relation to the other manifestations of the disease. Is the relief from tremor going to restore the patient's mental health, or will *paresis of the hand* or the analgesia be regarded as far worse than the tremor?

SECTION OF THE LATERAL COLUMN

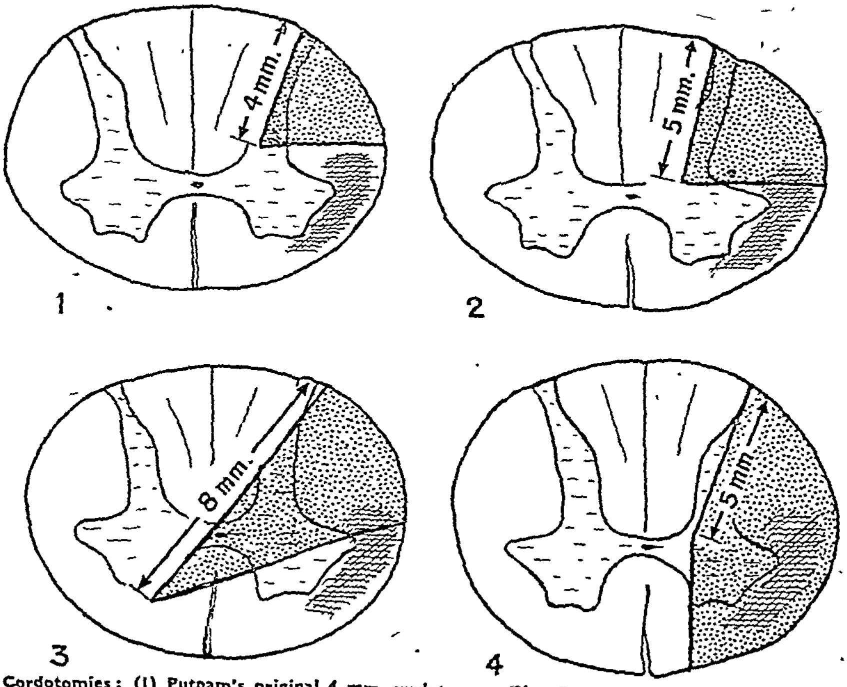
Anæsthesia

'Omnopon' gr. $^{1}/_{3}$ and hyoscine gr. $^{1}/_{150}$ are given subcutaneously an hour before the induction of anæsthesia. Immediately before the induction the patient's throat is sprayed with 10% cocaine solution. Anæsthesia is induced with a mixture of nitrous oxide, oxygen, and a little ether, and then an acrylic tube, size 9 or 10, is passed through the mouth into the trachea. The throat is packed, and the tube is threaded through a London Hospital airway. The tube is secured in place with strapping and then connected to the anæsthetic apparatus containing a carbon dioxide absorption unit. Anæsthesia is continued with nitrous oxide and oxygen, with the addition of a little ether or cyclopropane.

Operation

The patient's eyes are protected with cotton-wool held in place by adhesive elastic bandage. The patient is then placed in the "cerebellar position."

The incision extends from the seventh cervical spine to the external occipital protuberance. Pressure is applied to the skin edges by the assistants' fingers to control bleeding. The cut is extended through the deep fascia, to which fine artery forceps are applied, as to the galea aponeurotica in the case of incisions in the scalp. The weight of the forceps helps to control bleeding from the skin. Vessels which continue to bleed are coagulated by diathermy.



Cordotomies: (1) Putnam's original 4 mm. cordotomy; (2) a 5 mm. cordotomy involving the lateral spinothalamic tract; (3) Ebin's combined section of the lateral pyramidal and opposite ventral pyramidal tracts; and (4) complete section of the lateral column described here.

---

[1] Ebin, J. *Arch. Neurol. Psychiat.* 1949, 62, 27.
[2] Oliver, L. C. *Lancet,* 1949, i, 910.

Absolute hæmostasis is essential, for even a small ooze of blood may completely obscure the site of the cordotomy. For this reason the muscle-fibres attached to the spines and laminæ of the second and third cervical vertebræ are detached by diathermy.

The margins of the wound are separated with a self-retaining retractor. The spines and laminæ of the second and third cervical vertebræ are removed. The dura mater is incised longitudinally, and several traction sutures are inserted into the edges of the incision. The arachnoid is torn to expose the spinal cord. A no. 15 Bard-Parker blade is then clamped with an artery forceps so that 5 mm. of the blade projects beyond the beak of the forceps. With the cutting edge facing towards the anterior aspect of the cord, the point of the blade enters the cord at the site of attachment of a convenient posterior nerve-rootlet. The blade is pushed into the cord as far as the end of the artery forceps at an angle of 45°. The blade is then swept outwards. The depth of this incision is then checked with a blunt instrument—e.g., a blunt dura hook. The division of the lateral column is then completed with a blunt-ended tenotome. This instrument is inserted into the cord to the full depth of the incision, and then brought forward to emerge at the line of origin of the attachment of the anterior nerve-roots. Again the depth of the cut is checked with a blunt instrument.

The dura mater is closed with fine interrupted black silk sutures. The muscle is sutured in two layers, and the skin in one. Because the spinal membranes have been opened, a course of intramuscular penicillin is given.

POSTOPERATIVE COURSE

After operation there is a temporary hemiplegia on the side of the cordotomy with a permanent hemianalgesia and hemithermanæsthesia on the opposite side extending up to a level on the chest and sometimes including the arm. Horner's syndrome is present on the side of the operation. Babinski's reflex is also positive on this side.

Even after this radical procedure the hemiplegia usually begins quickly to recover. Recovery appears first in the leg, on the day after operation. Sometimes some return of movement will be observed at the elbow at the same time. In two or three weeks the patient will be walking unaided but with some dragging of the foot. The upper limb will be making good progress, but there will still be some weakness of the grip and loss of dexterity at this stage. Recovery of the paresis proceeds gradually, and will closely approach normal in most cases. The loss of sensation to pain and temperature on the opposite side is always permanent. After the more conservative operation which I described previously (5 mm. cordotomy) Horner's syndrome was not found, but it is always present after division of the whole lateral column. It usually improves and has never been a source of complaint.

Tremor.—There is immediate and complete relief from tremor in all cases, both in the arm and the leg. Usually there will be a slight return of tremor as the hemiplegia recovers, but it is present only when the patient is unduly excited. Division of the lateral column is more effective than either the original Putnam operation [3] (1 in figure) or the 5 mm. cordotomy (2 in figure).

RESULTS

I have done 79 cordotomies. In 6 a 4 mm. cut was made (Putnam), but the tremor returned to its former intensity in a few weeks, and in 55 a 5 mm. incision gave worth-while relief in 17 patients (33%)—the minimum follow-up time being twelve months. The best results, however, were obtained in the 18 patients in whom the whole lateral column was divided. With one exception all these patients were pleased with the result, and they were free from tremor except sometimes during moments of excitement.

The first cordotomy was done in October, 1947, and the last one, included in this report, six months ago. There were 5 deaths among the earlier patients. In each instance the parkinsonism was bilateral. The causes of death were: pneumonia in 3 cases, meningitis due to a coliform organism in 1 case, and unknown in 1 case. There have been no deaths after the complete division of the lateral column.

COMPLICATIONS

"*Rheumatoid Arthritis.*"—There were 3 patients who developed painful swelling of the wrist and finger joints on the side of the cordotomy, and clinically the condition was indistinguishable from rheumatoid arthritis. In each instance this complication arose after a 5 mm. cordotomy. There has been gradual improvement in all the patients.

Retention of urine lasted long enough to require catheterisation in 3 patients: the first was a man with an enlarged prostate; the second was the patient who developed meningitis; and the third was a man who had experienced the same difficulty after a cholecystectomy.

Acrocyanosis, affecting the upper limb on the side of the cordotomy, was seen in 2 patients.

Paræsthesia.—One patient complained of very unpleasant sensations like "electric shocks" in the leg on the side of the operation.

SUMMARY

A new operation for unilateral parkinsonian tremor is described, in which the whole lateral column of the spinal cord is divided on the side of the tremor.

The immediate effects of the operation are total absence of tremor, hemiplegia on the same side, and loss of sensation to pain and temperature on the opposite side. Later a little tremor is to be found at times of mental stress, and the hemiplegia usually recovers almost completely, but the hemianalgesia and hemithermanæsthesia are permanent.

Great care is essential in the selection of patients for operation. The disease must be confined to one side, and the surgeon must satisfy himself that cessation of the tremor will restore the patient's mental health.

FURTHER OBSERVATIONS ON THE POTENCY OF ŒSTROGENS

CLINICAL ASSESSMENT

P. M. F. Bishop

CHIEF ASSISTANTS, CHELSEA HOSPITAL FOR WOMEN

With statistical assistance from
W. L. M. Perry
M.D. St. And.

In a previous study (Bishop et al. 1948), the potencies of the synthetic œstrogens, stilbœstrol, dienœstrol, hexœstrol, and bis-dehydrodoisynolic acid were compared by observing their action in the production of uterine bleeding in women with amenorrhœa. In the present report the potencies of two further œstrogenic compounds, ethinyl œstradiol and "equine conjugated œstrogen," are compared with that of stilbœstrol by the same method of clinical assessment.

Ethinyl œstradiol is derived from œstradiol by substitution of the ethinyl group at the 17-carbon atom (Inhoffen and Hohlweg 1938). It has been used extensively during the past ten years in the United States, and more recently in this country, and has proved to be a highly effective œstrogen. There has, however, been considerable disagreement about the optimal dose. To relieve menopausal symptoms, for instance, Salmon et al. (1941) used an average daily dose of 0·45 mg.; Watson (1942) 0·15–0·45 mg.; Groper and Biskind (1942) 0·05–0·45 mg.; Birnberg et al. (1947) 0·15 mg.; Harding (1944) 0·05–0·1 mg.; and Soule (1943), Lyon (1944), and Wiesbader and Filler (1946) 0·05 mg. Allen (1944) estimates that it is seven and a half times as potent as stilbœstrol; Bickers (1946) that it is seventeen times as potent; Soule (1943) that it is from five to twenty times as potent; Gershenfeld and Perlmutter (1948) used 1·5 mg. daily to suppress lactation, and Jeffcoate et al. (1948) consider that it is more than fifty times, and possibly seventy times, as potent as stilbœstrol when used for this purpose.

"Equine conjugated œstrogen" is a term that may be used for the extract of œstrogenic substances from the urine of pregnant mares. The extract has been prepared by Ayerst, McKenna, and Harrison, in Canada, by collecting urine from pregnant mares kept in stables during the winter. The urine is immediately cooled to low temperatures by standing the collecting barrels out of doors. The resulting extract is a mixture of conjugated œstrogens, containing among other compounds œstrone sulphate, and seems to be considerably more potent than pure crystalline œstrone. In Canada and the United States this compound is marketed as 'Premarin.' The extract is distributed in this country by John Wyeth and Brother Ltd. under the trade name of 'Strogene.' Hamblen (1945) regards the ratio of dosage as stilbœstrol 1: premarin 1·25.

METHOD

The method of clinical assessment was the same as in the previous study, and the following description is quoted from Bishop et al. (1948):

> "The œstrogen was given by mouth in daily doses for a fortnight to induce 'withdrawal bleeding' within fourteen days of the last dose, the usual interval being from two to four days. The first course consisted of a 'sighting' dose (usually 2 mg. daily in the case of stilbœstrol). Depending on whether the response was positive or negative, the daily dose of the second course (the 'first bracketing' dose) was either lowered or raised—usually halved or doubled. The daily dose of the third course (the 'second bracketing' dose) was similarly adjusted according to the response of the first bracketing dose. In this way a 'therapeutic unit' was obtained, being the mean of the daily doses of two courses, one of which consisted of the highest, and the other of the lowest, daily dose to fail or succeed, respectively, to produce a withdrawal bleeding.
>
> "The patients selected had primary amenorrhœa, or secondary amenorrhœa of at least some months' standing.
>
> "In general an attempt was made first to determine the therapeutic unit of stilbœstrol, and subsequently the therapeutic unit of one or more of the other œstrogens, on the same patient."

RESULTS

Of the 62 patients studied, 52 had secondary amenorrhœa and 10 primary amenorrhœa; 462 courses of œstrogen were given; 47 therapeutic units of stilbœstrol, 38 of ethinyl œstradiol, and 23 of equine conjugated œstrogen were obtained.

The statistical analysis was carried out in the same way as that previously used by Dr. C. W. Emmens (Bishop et al. 1948). The logarithm of the ratio of the effective doses of two of the œstrogens on an individual patient was taken as the statistical unit. The potencies and limits of error thus reached were as follows, the comparisons being made with the therapeutic unit of stilbœstrol expressed as unity:

Substance	*No. of comparisons*	*Potency*	*Fiducial limits of error (P = 0·05)*
Ethinyl œstradiol	38	25·674	19·968–33·014 (77·8–128·6%)
Equine conjugated œstrogen	23	0·4949	0·2975–0·8231 (60·1–166·3%)

Since the scatter of the effective doses of any one œstrogen in different patients seemed to be much less than in the stilbœstrol-dienœstrol-hexœstrol-doisynolic acid series, the logarithms of the actual effective doses have been subjected to analysis of variance. The results of these analyses for the comparisons of ethinyl œstradiol and equine conjugated œstrogen against stilbœstrol are as follows.

Œstrogens compared	Degree of freedom	Sum of squares	Mean square	F	P
Stilbœstrol v. Ethinyl œstradiol:					
Between substances	1	25·0674	25·0674	199·62	< 0·001
Within substances	54	6·7812	0·1256	..	..
Total	55	31·8486	..	..	..
Stilbœstrol v. equine conjugated œstrogen:					
Between substances	1	1·5842	1·5842	10·18	0·001–0·01
Within substances	52	8·0940	0·1557	..	..
Total	53	9·6782	..	..	..

Potency ratios:
Ethinyl œstradiol v. stilbœstrol .. Potency ratio = 1 : 21·783
Equine conjugated œstrogen v. stilbœstrol .. .. Potency ratio = 1 : 0·4544

It will be seen that even with this form of analysis there are significant differences between these œstrogens, and the potency worked out on this basis very closely resembles that calculated by the original method.

"TOXICITY"

In the previous report it was shown that the "toxicity" range and the therapeutic range overlapped to such an extent in the case of stilbœstrol that it was possible to establish the probit-of-percentage-"toxicity"/log-dosage relationship, which was found to be linear, with a very good fit, indicating that "toxicity" virtually depended on dosage. This was not possible with any of the other œstrogens, because "toxicity" was so seldom met with in the doses administered that the data were quite insufficient for this type of statistical treatment. Thus the number of patients responding to treatment who complained of nausea at some time during the treatment was 36 out of 92 with stilbœstrol, but only 9 out of 129 with the other three œstrogens. Similarly, in the present series, the number of patients complaining of nausea when ethinyl œstradiol was being given was too few to enable a dose/"toxicity" curve to be constructed. Nevertheless, nausea was noted on several occasions; and in a higher dose range, such as is commonly used to check uterine flooding, nausea almost always occurs. "Toxic" effects were recorded in only one case of the equine conjugated œstrogen series, and some authorities say that so-called "toxic" effects are a manifestation of synthetic or partially synthetic compounds only, and never occur with "natural" œstrogens—i.e., those extracted from body-fluids or animal tissues. In 2 cases in which high doses of equine conjugated œstrogen were given for their hæmostatic effect (a total dose of 180 mg. in eight hours in both cases), however, both patients had severe nausea and vomiting and refused to continue with the treatment next day.

DISCUSSION

Choice of End-point

In the previous report (Bishop et al. 1948) reasons were given for our choice of œstrogen withdrawal bleeding in cases of amenorrhœa as the most suitable end-point for a clinical assessment of œstrogenic potency. These reasons may be briefly recapitulated here:

Other possible end-points are relief of menopausal symptoms, conversion of an atrophic to an œstrous type of vaginal smear, and suppression of lactation.

(1) *Relief of menopausal symptoms.* These symptoms are entirely subjective and difficult to assess quantitatively.

Absolute hæmostasis is essential, for even a small ooze of blood may completely obscure the site of the cordotomy. For this reason the muscle-fibres attached to the spines and laminæ of the second and third cervical vertebræ are detached by diathermy.

The margins of the wound are separated with a self-retaining retractor. The spines and laminæ of the second and third cervical vertebræ are removed. The dura mater is incised longitudinally, and several traction sutures are inserted into the edges of the incision. The arachnoid is torn to expose the spinal cord. A no. 15 Bard-Parker blade is then clamped with an artery forceps so that 5 mm. of the blade projects beyond the beak of the forceps. With the cutting edge facing towards the anterior aspect of the cord, the point of the blade enters the cord at the site of attachment of a convenient posterior nerve-rootlet. The blade is pushed into the cord as far as the end of the artery forceps at an angle of 45°. The blade is then swept outwards. The depth of this incision is then checked with a blunt instrument—e.g., a blunt dura hook. The division of the lateral column is then completed with a blunt-ended tenotome. This instrument is inserted into the cord to the full depth of the incision, and then brought forward to emerge at the line of origin of the attachment of the anterior nerve-roots. Again the depth of the cut is checked with a blunt instrument.

The dura mater is closed with fine interrupted black silk sutures. The muscle is sutured in two layers, and the skin in one. Because the spinal membranes have been opened, a course of intramuscular penicillin is given.

POSTOPERATIVE COURSE

After operation there is a temporary hemiplegia on the side of the cordotomy with a permanent hemianalgesia and hemithermanæsthesia on the opposite side extending up to a level on the chest and sometimes including the arm. Horner's syndrome is present on the side of the operation. Babinski's reflex is also positive on this side.

Even after this radical procedure the hemiplegia usually begins quickly to recover. Recovery appears first in the leg, on the day after operation. Sometimes some return of movement will be observed at the elbow at the same time. In two or three weeks the patient will be walking unaided but with some dragging of the foot. The upper limb will be making good progress, but there will still be some weakness of the grip and loss of dexterity at this stage. Recovery of the paresis proceeds gradually, and will closely approach normal in most cases. The loss of sensation to pain and temperature on the opposite side is always permanent. After the more conservative operation which I described previously (5 mm. cordotomy) Horner's syndrome was not found, but it is always present after division of the whole lateral column. It usually improves and has never been a source of complaint.

Tremor.—There is immediate and complete relief from tremor in all cases, both in the arm and the leg. Usually there will be a slight return of tremor as the hemiplegia recovers, but it is present only when the patient is unduly excited. Division of the lateral column is more effective than either the original Putnam operation [3] (1 in figure) or the 5 mm. cordotomy (2 in figure).

RESULTS

I have done 79 cordotomies. In 6 a 4 mm. cut was made (Putnam), but the tremor returned to its former intensity in a few weeks, and in 55 a 5 mm. incision gave worth-while relief in 17 patients (33%)—the minimum follow-up time being twelve months. The best results, however, were obtained in the 18 patients in whom the whole lateral column was divided. With one exception all these patients were pleased with the result, and they were free from tremor except sometimes during moments of excitement.

The first cordotomy was done in October, 1947, and the last one, included in this report, six months ago. There were 5 deaths among the earlier patients. In each instance the parkinsonism was bilateral. The causes of death were: pneumonia in 3 cases, meningitis due to a coliform organism in 1 case, and unknown in 1 case. There have been no deaths after the complete division of the lateral column.

COMPLICATIONS

"*Rheumatoid Arthritis.*"—There were 3 patients who developed painful swelling of the wrist and finger joints on the side of the cordotomy, and clinically the condition was indistinguishable from rheumatoid arthritis. In each instance this complication arose after a 5 mm. cordotomy. There has been gradual improvement in all the patients.

Retention of urine lasted long enough to require catheterisation in 3 patients: the first was a man with an enlarged prostate; the second was the patient who developed meningitis; and the third was a man who had experienced the same difficulty after a cholecystectomy.

Acrocyanosis, affecting the upper limb on the side of the cordotomy, was seen in 2 patients.

Paræsthesia.—One patient complained of very unpleasant sensations like "electric shocks" in the leg on the side of the operation.

SUMMARY

A new operation for unilateral parkinsonian tremor is described, in which the whole lateral column of the spinal cord is divided on the side of the tremor.

The immediate effects of the operation are total absence of tremor, hemiplegia on the same side, and loss of sensation to pain and temperature on the opposite side. Later a little tremor is to be found at times of mental stress, and the hemiplegia usually recovers almost completely, but the hemianalgesia and hemithermanæsthesia are permanent.

Great care is essential in the selection of patients for operation. The disease must be confined to one side, and the surgeon must satisfy himself that cessation of the tremor will restore the patient's mental health.

FURTHER OBSERVATIONS ON THE POTENCY OF ŒSTROGENS

CLINICAL ASSESSMENT

were made from the rats on the fourth and fifth days, and a positive response was recorded for all animals giving smears consisting of exclusively cornified cells or of cornified cells with sporadic nucleated epithelial cells. Stilbœstrol was used as the standard preparation.

The total number of positive responses in each dosage group was summed and expressed as a proportion of the total number of rats receiving that dose. From these results potencies and limits of error were calculated by the method for quantal responses described by Gaddum (1933).

With the exception of premarin all the substances examined were prepared in the research department of Boots Pure Drug Co. Ltd. The premarin was the commercial article marketed in tablets by Messrs. Ayerst. McKenna, and Harrison. This was stated to consist of naturally occurring œstrogens in their water-soluble form expressed as sodium œstrone sulphate. Because of the presence of other substances in the tablets it was assumed that all the tablets contained exactly the amount stated on the label. To extract the water-soluble material the tablets were broken, ground to a paste with water, and finally made up to a known volume with water. It was assumed that all the active material was extracted in this way.

RESULTS

The relative activities of the compounds examined together with those reported previously are given in the accompanying table.

DISCUSSION

For a biological assay technique to be satisfactory it not only must give reproducible results but should also give results which correspond with clinical findings. In our earlier experiments with stilbœstrol, hexœstrol, and dienœstrol the results we obtained agreed reasonably well with the clinical findings of Bishop et al. (1948). With 7-methyl-bis-dehydrodoisynolic acid and ethinyl œstradiol the picture was very different. On ovariectomised rats 7-methyl-bis-dehydrodoisynolic acid given by mouth was five times as active, and ethinyl œstradiol a fifth as active as stilbœstrol, whereas in patients 7-methyl-bis-dehydrodoisynolic acid was a fifth and ethinyl œstradiol twenty times as active as stilbœstrol.

From the point of view of the research-worker looking for new synthetic œstrogens these discrepancies are serious, since it may well be that clinically useful œstrogens have been discarded because of unfavourable results in tests on animals.

The difference between results in patients and those in animals may be due to several causes. Parkes et al. (1938) have suggested that the effectiveness of œstrogens given by mouth depends largely on the conditions of absorption from the alimentary tract, which differ widely from species to species. The mechanism of metabolism may also vary from species to species. Many workers have shown that œstrogens are inactivated in the liver, and Heller (1940) has shown that œstradiol is also inactivated in the rabbit's kidney but not in the rat's kidney. Finally, the rate of excretion may also vary between species.

RELATIVE ACTIVITIES OF ŒSTROGENS GIVEN BY MOUTH AND SUBCUTANEOUSLY

Œstrogen	By mouth		Subcutaneously	
	Activity	P = 0·95 limits of error	Activity	P = 0·95 limits of error
Stilbœstrol	100	(assumed)	100	(assumed)
Hexœstrol	10	8·5–11·7	66	64–68
Dienœstrol	68	63–73	28	27–29
Potassium hexœstrol sulphate	7·3	6·7–8·0	0·98	0·91–1·05
7-methyl-bis-dehydro-doisynolic acid.. ..	500	445–560	46	41–51
Œstrone	2	1·6–2·4	29	28–30
Premarin	5	..	8	..
Ethinyl œstradiol ..	18	14–23	233	191–285
Divinyl stilbœstrol ..	103	75–142	45	22–91

Whatever may be the correct explanation of the difference between the biological results and the clinical findings, it seems clear that, whereas existing biological techniques will detect œstrogenic action in a new substance, a clinical assay is necessary before the value of a new œstrogen relative to existing preparations can be established. We are therefore fortunate in having available the withdrawal-bleeding assay method described by Bishop et al. (1948, 1950). This method is particularly valuable in that the data obtained can be statistically treated and the limits of error of any particular assay determined. It is in fact a biological assay on patients. Its main disadvantage is the long time taken to carry out a test. There is therefore still an urgent need for a biological assay technique which will give the same answer as the clinical method.

SUMMARY

Large-scale experiments designed to assay the œstrogenic activity of various œstrogens have been made with ovariectomised adult female rats.

The results obtained in some cases agree with clinical findings, but in others the biological and clinical results differ considerably.

The significance of these discrepancies is discussed.

IN the last decade the study of thyroid disease has received considerable impetus from the development of techniques using radioactive iodine, and from the discovery of the antithyroid action of certain drugs such as thiouracil. We report here a hitherto unrecognised antithyroid substance which has been discovered from the clinical application of these radioactive techniques: instances of clinical myxœdema have been encountered resulting from this antithyroid substance, which is different chemically from the already known antithyroid agents.

An unexpected result with a radioactive-iodine test was reported by Rawson et al. (1943) in a case of myxœdema with goitre due to previous long-continued administration of thiocyanate for hypertension. He found that this patient's thyroid gland took up the iodine as avidly as the gland of hyperthyroid patients. This finding has since been clarified. Vanderlaan and Vanderlaan (1947) showed that when thiocyanate circulates in the blood above a critical level (10 mg. per 100 ml.), it inhibits the thyroid's ability to concentrate iodine, and so to form an adequate supply of thyroid hormone. Consequently, with its continued administration, there develops thyroid deficiency together with a hyperplastic

---

* The expenses of the investigation were partly met by a grant from the Medical Research Council.

Even if the daily hot-flush count were accepted as a semi-quantitative end-point, considerable alterations in the count would have to occur to be significant, and after each course of œstrogen which gave a positive result the hot-flush count would have to be allowed to return to its pre-treatment base-line. At least two œstrogens would have to be tested on each patient. The assessment might therefore take many months, during which the œstrogenic status of the patient might be constantly changing. Finally, the patient would be disinclined to endure the series of relapses which the return to the base-line after each course of effective œstrogen therapy would entail.

(2) *Changes in the vaginal smear.* It has seldom been our experience to encounter menopausal women with a sufficiently labile smear to change from the atrophic to the œstrous condition and vice versa quickly enough to allow assessment of at least two œstrogens by this method.

(3) *Suppression of lactation.* Only one course of œstrogen is given to succeed or fail to suppress lactation in any one patient on one occasion. It is therefore impossible to compare two œstrogens in the same patient.

There are variables in the present method which might have been expected to vitiate the results seriously—such as the possibility of occasional spontaneous periods being mistaken for withdrawal bleedings, or of the level of response in any one patient varying during the investigation. That such variables did not in fact seriously affect the results seems clear from the statistical analysis.

Comparison of Clinical Assessment and Animal Assay

Harmer and Broom (1948) conducted large-scale experiments to assess the œstrogenic activity of certain synthetic œstrogens in ovariectomised adult female rats, and found that, given by mouth, hexœstrol was a tenth and dienœstrol two-thirds as active as stilbœstrol. These ratios did not exactly correspond with those established in the clinical experiments of Bishop et al. (1948), who found hexœstrol an eighteenth and dienœstrol a quarter as potent as stilbœstrol, but the animal and human studies agreed in establishing that stilbœstrol was the most potent, dienœstrol the next most potent, and hexœstrol the least potent, of the three œstrogens, the results differing in degree only.

In the present studies, however, there is more fundamental disagreement between the results, for Harmer and Broom (1950) find ethinyl œstradiol to be a less potent œstrogen in rats than stilbœstrol. Furthermore, they find bis-dehydrodoisynolic acid to be more active than stilbœstrol, whereas Bishop et al. (1948) found it to be less active. It seems clear therefore that one is not justified in depending on the result of animal assays to determine the relative potency of œstrogens in the human subject.

It is also possible that the ratios of potencies may change at different levels of œstrogenic response, and that one is not justified in accepting the ratios given in this study as applying, for instance, to relief of menopausal symptoms on the one hand, or to suppression of lactation or treatment of inoperable carcinoma of the breast or prostate on the other.

SUMMARY

A method is described for comparing the potency of œstrogens in the human subject. It consists in giving the œstrogen daily by mouth in fourteen-day courses to amenorrhœic women and recording whether œstrogen-withdrawal bleeding takes place.

The results obtained indicate that ethinyl œstradiol is 20–25 times as potent as stilbœstrol, and equine conjugated œstrogen half as potent.

Few cases of nausea were encountered with ethinyl œstradiol at the therapeutic levels necessary to induce withdrawal bleeding, and only one case of nausea occurred with equine conjugated œstrogen. At higher dosage levels, however, such as those necessary to produce hæmostasis in cases of functional uterine bleeding, "toxic" effects usually developed with ethinyl œstradiol, and in 2 such patients given equine conjugated œstrogen (a natural œstrogenic product) severe vomiting was caused by high dosage. "Toxicity" does not therefore depend on whether the compound is wholly or partially synthetic or whether it is extracted entirely from natural sources.

Reasons are given for choosing this end-point and for the failure to devise any other suitable method of assessment at different levels of œstrogenic response, such as relief of menopausal symptoms, the production of an œstrous vaginal smear, or the suppression of lactation.

We wish to thank Sir Jack Drummond, F.R.S., for facilities to enable us to carry out this work; Mr. P. Keddie, of John Wyeth and Brother Ltd., for supplies of strogene; and Dr. Perry for his statistical work in connection with this study. The ethinyl œstradiol was supplied by The British Drug Houses Ltd., Messrs. Ciba Ltd., Organon Ltd., and Roussel Ltd.

ACTIVITY OF SOME FURTHER SYNTHETIC ŒSTROGENS DETERMINED BY EXPERIMENTS ON RATS

G. L. M. Harmer
B.Sc. Lond.

W. A. Broom
B.Sc. Lond., F.R.I.C.

From the Pharmacology and Physiology Division, Research Department, Boots Pure Drug Co. Ltd., Nottingham

In a previous paper (Harmer and Broom 1948) we described experiments in which we determined the relative activity on ovariectomised rats of the three synthetic œstrogens: stilbœstrol, dienœstrol, and hexœstrol. Our results agreed with those published by Kemp and Pedersen-Bjergaard (1943) and were in substantial agreement with the findings of Bishop et al. (1948), who examined their relative clinical efficiencies.

We have now extended our experiments to include other œstrogens of clinical interest, and have examined ethinyl œstradiol, 7-methyl-*bis*-dehydrodoisynolic acid, 'Premarin,' divinyl stilbœstrol, and sodium stilbœstrol sulphate. The results of these experiments are of particular interest in the light of the clinical findings of Bishop et al. (1950).

METHODS

The experimental techniques are essentially the same as those reported earlier (Harmer and Broom 1948), but a brief résumé of the details is given here.

Inbred Wistar rats ovariectomised at 7–8 weeks were used. The completeness of the ovariectomy was checked by taking vaginal smears during the 10–20 days after the operation, and only those animals in continuous anœstrus during the whole of this period were used for experiment. The substance under test was given, either once daily by stomach-tube or injected subcutaneously twice daily, for three days. Vaginal smears

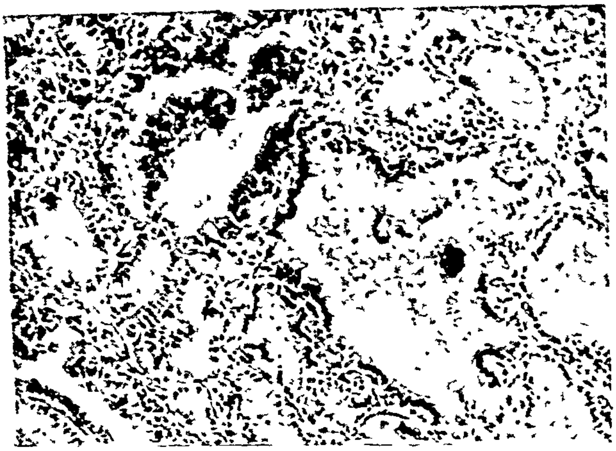

Fig. 4—Section of thyroid gland (× 90) post mortem in case I.

face and eyes were puffy and her features heavy; her hair was dry, and her skin, especially on the face, arms, knees, and feet, dry and scaly; her palms and soles were grossly hyperkeratotic. All these features, she insisted, were recent. Her nails were normal.

The pulse-rate was 72 per min., and blood-pressure 110/80 mm. Hg. The jugular venous pressure was not raised; the apex-beat was 4½ in. from the midline in the 5th intercostal space; and the heart sounds were normal. She showed moderate kyphoscoliosis, a few crepitations at the base of the right lung, and a few generalised rhonchi. Palpation of the neck revealed a very soft, diffusely enlarged thyroid gland, with to-and-fro audible bruits; its weight was estimated at 100 g. Its size and its vascularity were later confirmed both by I^{131} measurement and by biopsy inspection. Moderate œdema was evident in both legs, but not elsewhere; over most of the circumference of the left leg just above the ankle was a very large, grossly purulent ulcer. A similar, smaller ulcer was present just above the right external malleolus (fig. 6).

Investigations.—The patient was admitted for investigation on Feb. 7, 1950, when the ointment application was stopped. Urine: no abnormality. X-ray examination of the chest showed some increased basal markings, and appreciable transverse enlargement of the heart involving both ventricles. Hb 12.5 g. per 100 ml. (85%). E.C.G. revealed left bundle-branch block and a small anterior myocardial infarct, but otherwise normal complexes and voltage.

Findings confirming thyroid deficiency included: on Jan. 31 plasma-cholesterol 316 mg. per 100 ml., plasma-proteins 8·4 g. per 100 ml. (albumin-globulin ratio 1 : 1), and protein-bound iodine under 1 γ per 100 ml. B.M.R. (Feb. 9) 14%. C.S.F. normal apart from protein 60 mg. per 100 ml. An intravenous insulin-tolerance test (Feb. 20) showed an abnormality consistent with myxœdema—i.e., a slightly delayed fall and subsequent rise and no hypoglycæmic symptoms. The readings were as follows:

		Blood-sugar, mg. per 100 ml.
Fasting		99
Min. after glucose:	20	58
	30	51
	45	51
	60	68
	90	77
	120	87

A radioactive-iodine uptake test (Feb. 10) showed a very low urinary excretion—6% in 48 hours (4·1% in 0–8 hr., 0.8% in 8–24 hr., and 1·1% in 24–48 hr.)—and a high thyroid uptake (62% at 73 hours). This finding was inconsistent with spontaneous myxœdema and suggested previous long-continued administration of an antithyroid drug (fig. 3).

Thyroid biopsy on Feb. 14 (fig. 6) confirmed this indication, showing a hyperplastic gland made up of small and medium-sized follicles empty of colloid and lined by high cuboidal and columnar epithelium often showing papilliform infolding. There was moderate œdema of the interstitial tissue, which showed no lymphoid infiltration.

Progress.—From Feb. 7 to 20 the resorcinol ointment was not applied; and the patient noticed significant recession in the myxœdematous symptoms and features—a change also observed by us. The same ointment was then applied once more to her leg from Feb. 21 to March 13. On its subsequent withdrawal, improvement was again noticed, and her normal general health was restored without any medication (fig. 5B). Measurements of thyroid function during a further fortnight's application of the ointment and a further fortnight after withdrawal confirmed the antithyroid effects of applying this ointment to the ulcers.

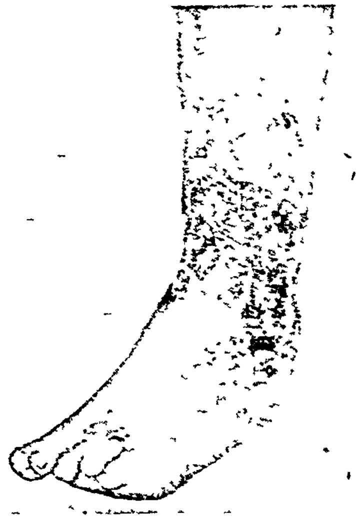

Fig. 6—Varicose leg ulcer in case 2.

Case 3.—The patient, a housewife aged 50, with five children, was admitted to Fulham Hospital under the care of Dr. R. J. Harrison. For 2 years she had noticed increasing effort dyspnœa and sensitivity to cold, for 1 year general slowness and anergia; and for 7 months anorexia, irritable depression with poor memory and insomnia, husky voice, thinning of the scalp hair, and dry skin.

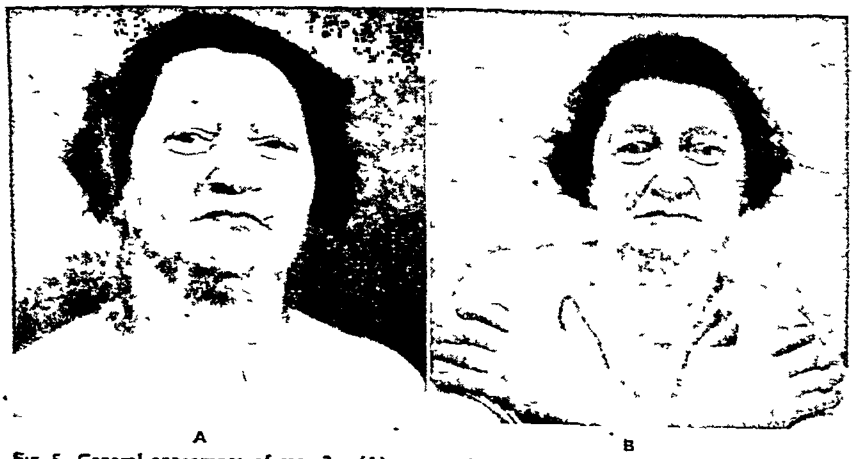

Fig. 5—General appearance of case 2: (A) one week after last resorcinol application; (B) on discharge from hospital, 35 days after finally ceasing resorcinol application.

She had always had good health until 1943, when an attack of pneumonia was complicated by a left white-leg, which soon became complicated by a varicose ulcer which has never yet healed. For the past 3 years she had been applying to the ulcer ung. resorcini co. *B.P.C.* (4% resorcinol) using about 1 lb. per week. She had not been taking other drugs or unusual diet. For the last 2 years she had noticed swelling of the neck. She had also had two attacks of "jaundice"—one 3 years ago, lasting a month without pain or abnormal motions, and another 7 months ago lasting 4 months and associated at its onset with two weeks of vomiting and various pains; both attacks subsided spontaneously. Since the first attack she had been pale, depressed, and lethargic. For the first fortnight of the second, she also suffered

goitre, just as in severe iodine deficiency. Only so long as the high blood-level of the thiocyanate is maintained is this hyperplastic gland prevented from concentrating iodine. When the thiocyanate administration is stopped, and the blood-thiocyanate concentration rapidly falls below the critical level, the unfettered hyperplastic gland takes up iodine avidly. When Rawson's patient was admitted for investigation the thiocyanate administration had been stopped, which explains the unexpectedly high iodine uptake which he found.

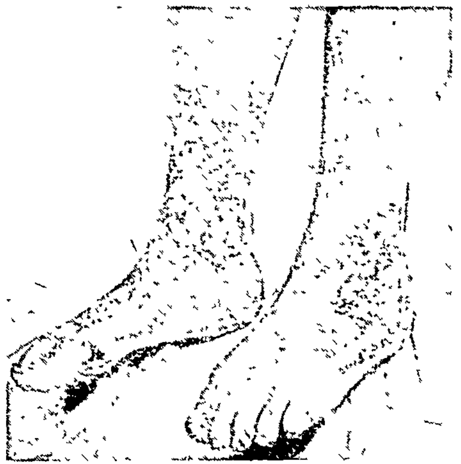

Fig. 1—Varicose leg ulcers in case 1.

Excessive uptake of iodine by the gland of a patient with myxœdema has therefore become the hallmark of myxœdema resulting from previous prolonged administration of an antithyroid agent. It was a similar finding with a radioactive iodine-uptake test in our patients which led ultimately to the conclusion that their myxœdema was due to resorcinol absorbed from the ointment applied to their varicose ulcers.

CASE-REPORTS

Case 1.—This patient, a 60-year-old housewife, had been under observation since 1936. At the age of 9 years she had had rheumatic fever; and in 1945 she was admitted with cardiac failure apparently consequent on mitral stenosis. Thereafter she was more or less continuously in some degree of heart-failure, from which she ultimately died in June, 1949.

The significant history relating to her myxœdema began in 1936 when she developed extensive bilateral ulceration of the legs after an injection for varicose veins. Despite Trendelenburg operations on both legs in 1945, these ulcers never healed. In October, 1948, she was admitted to hospital because of gross cardiac failure with extensive œdema.

Condition on admission.—Her weight was 14 st. 3 lb. (90 kg.), and she had large dirty ulcers on both legs (fig. 1). Certain features suggested that she might be mildly thyrotoxic. In addition to auricular fibrillation, which might have been due to the mitral stenosis, she had slight tremor of the hands, a warm periphery with sweating palms, and a blood-pressure of 150/60 mm. Hg. Neither thyroid enlargement nor abnormal eye signs were noted. The basal metabolic rate (B.M.R.) was + 25%, and the arm-to-tongue circulation-time (saccharin method) was 17 sec. An electrocardiograph (E.C.G.) showed normal voltage of the Q R S complex (fig. 2A).

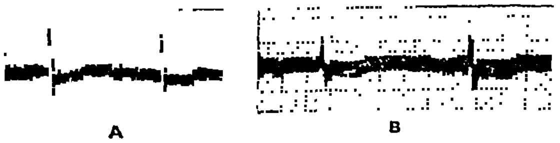

Fig. 2—E.C.G., lead 2, in case 1: (A) Oct. 2, 1948; (B) June 15, 1949.

Progress.—When seen again in the outpatient department in December, 1948, her condition appeared unchanged.

Readmission.—When the patient was readmitted on June 14, 1949, a striking change in her appearance was apparent. During the previous six weeks dyspnœa had increased considerably, and she had noticed a gain in weight. She had also noticed since the last admission a gradual increase in the size of her neck and gradually increasing dysphagia and hoarseness of voice. The only medication she had received since the previous admission was digitalis folia gr. 1 twice daily and applications of resorcinol ointment to the legs.

She now weighed 17 st. 10 lb. (112·5 kg.)—a gain of 49 lb. (22·3 kg.) in seven months. Her hair was coarse, her skin dry, and her general appearance myxœdematous. The thyroid gland was considerably and diffusely enlarged and firm, but neither nodular nor hard. She was in gross cardiac failure and her arm-to-tongue circulation-time was now 28 sec. The blood-pressure was 126/84 mm. Hg and an E.C.G. now showed low voltage and flat T waves (fig. 2B). The plasma-cholesterol was 192 mg. per 100 ml. and the protein-bound iodine under 1 γ per 100 ml. (normal 4–8 γ); the cerebrospinal fluid (C.S.F.) protein content was 100 mg. per 100 ml. A radioactive urinary iodine-excretion test (Arnott et al. 1949) on June 17 showed an extremely low excretion suggesting an avid uptake by the thyroid gland: 7·6% in 0–48 hr. (3% in 0–8 hr., 2·5% in 8–24 hr., and 2·1% in 24–48 hr.); and 2·3% in 48–72 hr. (fig. 3).

On the patient's admission to hospital, her legs were dressed with plain tulle gras, and the cardiac failure was treated with low-salt diet, rest in bed, and digitalis. For the first few days after admission her condition improved, but on June 26 her cardiac condition deteriorated and she died next day.

Necropsy confirmed the presence of rheumatic heart-disease with cardiac failure. The thyroid gland was about four times normal size (130 g.), and was pale and fleshy with a normal capsule. Histologically (fig. 4) the gland showed gross parenchymatous hyperplasia, with small and large follicles, mostly depleted of colloid, lined by columnar epithelium rich in papilliform infoldings. There were occasional islets, a few millimetres across, of hyperplastic follicles filled with peripherally vacuolated colloid. The gland was traversed by numerous thickened fibrous trabeculæ. It showed very occasional scattered lymphocytes but no lymphoid follicles, strongly suggesting that the hyperplasia was a response to a goitrogen rather than thyrotoxicosis.

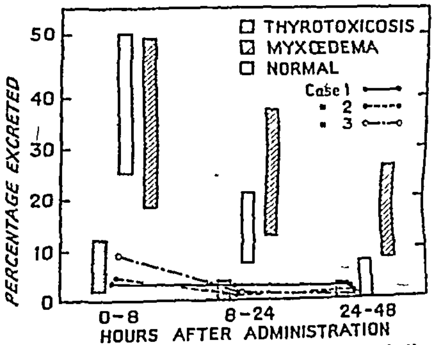

Fig. 3—Urinary excretion of radioactive iodine from each of the 3 patients, compared with the range of findings (mean, S.D. ± 2) in 30 normals, 35 obvious thyrotoxic patients, and 10 patients with typical spontaneous myxœdema.

Case 2.—A normally active housewife, aged 59 years, who was the mother of seven children, attended the outpatient department on Jan. 31, 1950, complaining of a series of symptoms which she insisted had all developed over the last two months. For two months she had noticed tiredness with backache, for six weeks tinnitus and deafness, for four weeks dyspnœa with substernal anginal pain on effort, and for two weeks anorexia, unusual sensitivity to cold, puffiness and dry scaliness of the face and arms, hoarseness, and slight cough without sputum.

Previously she had had a normal menopause at the age of 49, and had always had good general health except for varicose veins and ulcers on both legs. For 12 years she had been liable to evening swelling of the legs. She had never previously sought a doctor's advice, although for 23 years the leg ulcers had never healed. For the past 2 years she had been dressing these with a chemist's ointment three times daily, using approximately 4–6 oz. per week; this was ascertained to be 12% resorcinol in glycerin, paraffin, and lanoline. She had taken no other medicines, and her diet was not abnormal.

Examination.—The patient had a typical myxœdematous appearance (fig. 5A). Her weight, usually about 10 st., was 11st. 11 lb. (75 kg.). She was moderately obese with supraclavicular pads and a rather prominent abdomen. Her

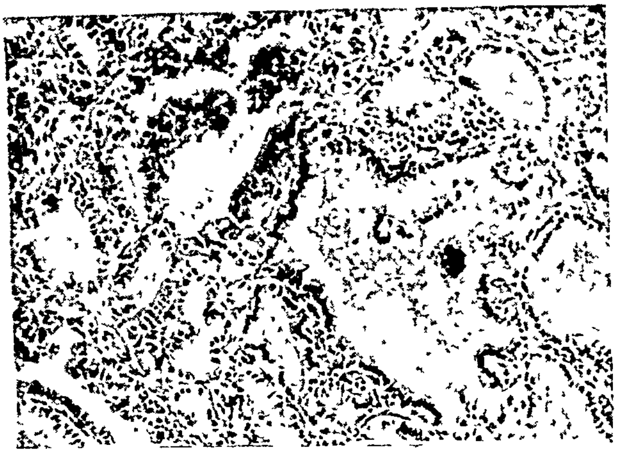

Fig. 4—Section of thyroid gland (× 90) post mortem in case I.

face and eyes were puffy and her features heavy; her hair was dry, and her skin, especially on the face, arms, knees, and feet, dry and scaly; her palms and soles were grossly hyperkeratotic. All these features, she insisted, were recent. Her nails were normal

The pulse-rate was 72 per min, and blood-pressure 110/80 mm. Hg. The jugular venous pressure was not raised; the apex-beat was 4½ in. from the midline in the 5th intercostal space; and the heart sounds were normal. She showed moderate kyphoscoliosis, a few crepitations at the base of the right lung, and a few generalised rhonchi. Palpation of the neck revealed a very soft, diffusely enlarged thyroid gland, with to-and-fro audible bruits; its weight was estimated at 100 g. Its size and its vascularity were later confirmed both by I^{131} measurement and by biopsy inspection. Moderate œdema was evident in both legs, but not elsewhere; over most of the circumference of the left leg just above the ankle was a very large, grossly purulent ulcer. A similar, smaller ulcer was present just above the right external malleolus (fig. 6).

Investigations.—The patient was admitted for investigation on Feb. 7, 1950, when the ointment application was stopped. Urine: no abnormality. X-ray examination of the chest showed some increased basal markings, and appreciable transverse enlargement of the heart involving both ventricles. Hb 12·5 g. per 100 ml (85%). E.C.G. revealed left bundle-branch block and a small anterior myocardial infarct, but otherwise normal complexes and voltage.

Findings confirming thyroid deficiency included: on Jan. 31 plasma-cholesterol 316 mg. per 100 ml., plasma-proteins 8·4 g. per 100 ml. (albumin-globulin ratio 1 : 1), and protein-bound iodine under 1 γ per 100 ml. B.M.R. (Feb. 9) 14%. C.S.F. normal apart from protein 60 mg. per 100 ml. An intravenous insulin-tolerance test (Feb. 20) showed an abnormality consistent with myxœdema—i.e., a slightly delayed fall and subsequent rise and no hypoglycæmic symptoms. The readings were as follows:

		Blood-sugar, mg. per 100 ml.
Fasting		99
Min. after glucose:	20	58
	30	51
	45	51
	60	68
	90	77
	120	87

A radioactive-iodine uptake test (Feb. 10) showed a very low urinary excretion—6% in 48 hours (4·1% in 0–8 hr., 0·8% in 8–24 hr., and 1·1% in 24–48 hr.)—and a high thyroid uptake (62% at 73 hours). This finding was inconsistent with spontaneous myxœdema and suggested previous long-continued administration of an antithyroid drug (fig. 3).

Thyroid biopsy on Feb. 14 (fig. 6) confirmed this indication, showing a hyperplastic gland made up of small and medium-sized follicles empty of colloid and lined by high cuboidal and columnar epithelium often showing papilliform infolding. There was moderate œdema of the interstitial tissue, which showed no lymphoid infiltration.

Progress.—From Feb. 7 to 20 the resorcinol ointment was not applied; and the patient noticed significant recession in the myxœdematous symptoms and features—a change also observed by us. The same ointment was then applied once more to her leg from Feb. 21 to March 13. On its subsequent withdrawal, improvement was again noticed, and her normal general health was restored without any medication (fig. 5B). Measurements of thyroid function during a further fortnight's application of the ointment and a further fortnight after withdrawal confirmed the antithyroid effects of applying this ointment to the ulcers.

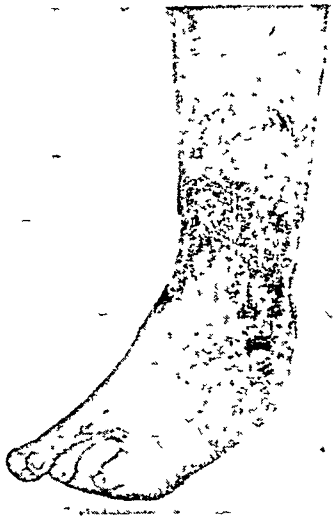

Fig. 6—Varicose leg ulcer in case 2.

Case 3.—The patient, a housewife aged 50, with five children, was admitted to Fulham Hospital under the care of Dr. R. J. Harrison. For 2 years she had noticed increasing effort dyspnœa and sensitivity to cold, for 1 year general slowness and anergia; and for 7 months anorexia, irritable depression with poor memory and insomnia, husky voice, thinning of the scalp hair, and dry skin.

Fig. 5—General appearance of case 2: (A) one week after last resorcinol application; (B) on discharge from hospital, 35 days after finally ceasing resorcinol application.

She had always had good health until 1943, when an attack of pneumonia was complicated by a left white-leg, which soon became complicated by a varicose ulcer which has never yet healed. For the past 3 years she had been applying to the ulcer ung. resorcini co. *B.P.C.* (4% resorcinol) using about 1 lb. per week. She had not been taking other drugs or unusual diet. For the last 2 years she had noticed swelling of the neck. She had also had two attacks of "jaundice"—one 3 years ago, lasting a month without pain or abnormal motions, and another 7 months ago lasting 4 months and associated at its onset with two weeks of vomiting and various pains; both attacks subsided spontaneously. Since the first attack she had been pale, depressed, and lethargic. For the first fortnight of the second, she also suffered

goitre, just as in severe iodine deficiency. Only so long as the high blood-level of the thiocyanate is maintained is this hyperplastic gland prevented from concentrating iodine. When the thiocyanate administration is stopped, and the blood-thiocyanate concentration rapidly falls below the critical level, the unfettered hyperplastic gland takes up iodine avidly. When Rawson's patient was admitted for investigation the thiocyanate administration had been stopped, which explains the unexpectedly high iodine uptake which he found.

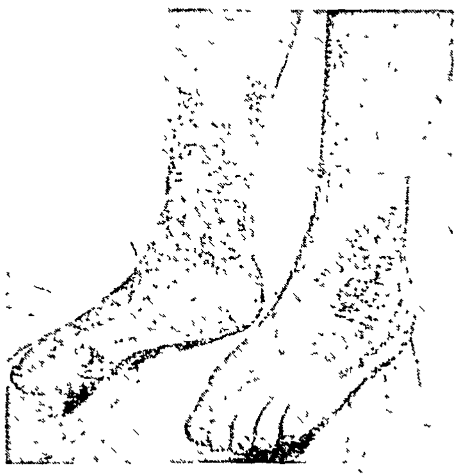

Fig. 1—Varicose leg ulcers in case 1.

Excessive uptake of iodine by the gland of a patient with myxœdema has therefore become the hallmark of myxœdema resulting from previous prolonged administration of an antithyroid agent. It was a similar finding with a radioactive iodine-uptake test in our patients which led ultimately to the conclusion that their myxœdema was due to resorcinol absorbed from the ointment applied to their varicose ulcers.

CASE-REPORTS

Case 1.—This patient, a 60-year-old housewife, had been under observation since 1936. At the age of 9 years she had had rheumatic fever; and in 1945 she was admitted with cardiac failure apparently consequent on mitral stenosis. Thereafter she was more or less continuously in some degree of heart-failure, from which she ultimately died in June, 1949.

The significant history relating to her myxœdema began in 1936 when she developed extensive bilateral ulceration of the legs after an injection for varicose veins. Despite Trendelenburg operations on both legs in 1945, these ulcers never healed. In October, 1948, she was admitted to hospital because of gross cardiac failure with extensive œdema.

Condition on admission.—Her weight was 14 st. 3 lb. (90 kg.), and she had large dirty ulcers on both legs (fig. 1). Certain features suggested that she might be mildly thyrotoxic. In addition to auricular fibrillation, which might have been due to the mitral stenosis, she had slight tremor of the hands, a warm periphery with sweating palms, and a blood-pressure of 150/60 mm. Hg. Neither thyroid enlargement nor abnormal eye signs were noted. The basal metabolic rate (B.M.R.) was + 25%, and the arm-to-tongue circulation-time (saccharin method) was 17 sec. An electrocardiograph (E.C.G.) showed normal voltage of the Q R S complex (fig. 2A).

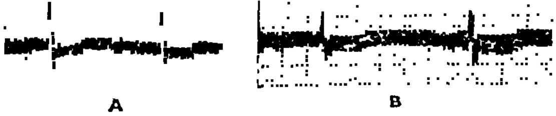

Fig. 2—E.C.G., lead 2, in case 1: (A) Oct. 2, 1948; (B) June 15, 1949.

Progress.—When seen again in the outpatient department in December, 1948, her condition appeared unchanged.

Readmission.—When the patient was readmitted on June 14, 1949, a striking change in her appearance was apparent. During the previous six weeks dyspnœa had increased considerably, and she had noticed a gain in weight. She had also noticed since the last admission a gradual increase in the size of her neck and gradually increasing dysphagia and hoarseness of voice. The only medication she had received since the previous admission was digitalis folia gr. 1 twice daily and applications of resorcinol ointment to the legs.

She now weighed 17 st. 10 lb. (112·5 kg.)—a gain of 49 lb. (22·3 kg.) in seven months. Her hair was coarse, her skin dry, and her general appearance myxœdematous. The thyroid gland was considerably and diffusely enlarged and firm, but neither nodular nor hard. She was in gross cardiac failure and her arm-to-tongue circulation-time was now 28 sec. The blood-pressure was 126/84 mm. Hg and an E.C.G. now showed low voltage and flat T waves (fig. 2B). The plasma-cholesterol was 192 mg. per 100 ml. and the protein-bound iodine under 1 γ per 100 ml. (normal 4–8 γ); the cerebrospinal fluid (C.S.F.) protein content was 100 mg. per 100 ml. A radioactive urinary iodine-excretion test (Arnott et al. 1949) on June 17 showed an extremely low excretion suggesting an avid uptake by the thyroid gland: 7·6% in 0–48 hr. (3% in 0–8 hr., 2·5% in 8–24 hr., and 2·1% in 24–48 hr.); and 2·3% in 48–72 hr. (fig. 3).

On the patient's admission to hospital, her legs were dressed with plain tulle gras, and the cardiac failure was treated with low-salt diet, rest in bed, and digitalis. For the first few days after admission her condition improved, but on June 26 her cardiac condition deteriorated and she died next day.

Necropsy confirmed the presence of rheumatic heart-disease with cardiac failure. The thyroid gland was about four times normal size (130 g.), and was pale and fleshy with a normal capsule. Histologically (fig. 4) the gland showed gross parenchymatous hyperplasia, with small and large follicles, mostly depleted of colloid, lined by columnar epithelium rich in papilliform infoldings. There were occasional islets, a few millimetres across, of hyperplastic follicles filled with peripherally vacuolated colloid. The gland was traversed by numerous thickened fibrous trabeculæ. It showed very occasional scattered lymphocytes but no lymphoid follicles, strongly suggesting that the hyperplasia was a response to a goitrogen rather than thyrotoxicosis.

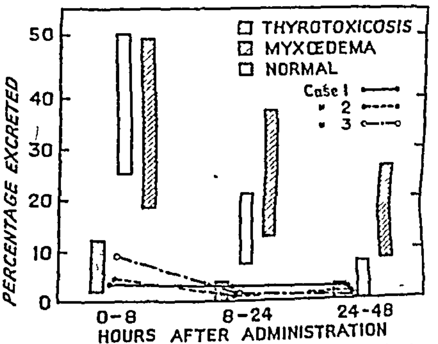

Fig. 3—Urinary excretion of radioactive iodine from each of the 3 patients, compared with the range of findings (mean, S.D. ± 2) in 30 normals, 35 obvious thyrotoxic patients, and 10 patients with typical spontaneous myxœdema.

Case 2.—A normally active housewife, aged 59 years, who was the mother of seven children, attended the outpatient department on Jan. 31, 1950, complaining of a series of symptoms which she insisted had all developed over the last two months. For two months she had noticed tiredness with backache, for six weeks tinnitus and deafness, for four weeks dyspnœa with substernal anginal pain on effort, and for two weeks anorexia, unusual sensitivity to cold, puffiness and dry scaliness of the face and arms, hoarseness, and slight cough without sputum.

Previously she had had a normal menopause at the age of 49, and had always had good general health except for varicose veins and ulcers on both legs. For 12 years she had been liable to evening swelling of the legs. She had never previously sought a doctor's advice, although for 23 years the leg ulcers had never healed. For the past 2 years she had been dressing these with a chemist's ointment three times daily, using approximately 4–6 oz. per week; this was ascertained to be 12% resorcinol in glycerin, paraffin, and lanoline. She had taken no other medicines, and her diet was not abnormal.

Examination.—The patient had a typical myxœdematous appearance (fig. 5A). Her weight, usually about 10 st., was 11st. 11 lb. (75 kg.). She was moderately obese with supraclavicular pads and a rather prominent abdomen. Her

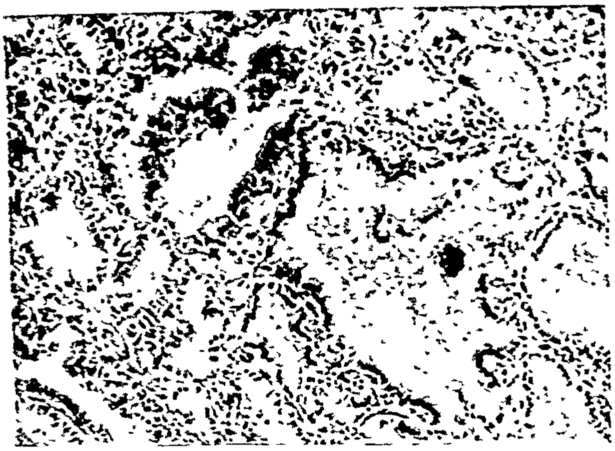

Fig. 4—Section of thyroid gland (× 90) post mortem in case 1.

face and eyes were puffy and her features heavy; her hair was dry, and her skin, especially on the face, arms, knees and feet, dry and scaly; her palms and soles were grossly hyperkeratotic. All these features, she insisted, were recent. Her nails were normal.

The pulse-rate was 72 per min., and blood-pressure 110/80 mm. Hg. The jugular venous pressure was not raised; the apex-beat was 4$^1/_2$ in. from the midline in the 5th intercostal space; and the heart sounds were normal. She showed moderate kyphoscoliosis, a few crepitations at the base of the right lung, and a few generalised rhonchi. Palpation of the neck revealed a very soft, diffusely enlarged thyroid gland, with to-and-fro audible bruits; its weight was estimated at 100 g. Its size and its vascularity were later confirmed both by I^{131} measurement and by biopsy inspection. Moderate œdema was evident in both legs, but not elsewhere; over most of the circumference of the left leg just above the ankle was a very large, grossly purulent ulcer. A similar, smaller ulcer was present just above the right external malleolus (fig. 6).

Investigations.—The patient was admitted for investigation on Feb. 7, 1950, when the ointment application was stopped. Urine: no abnormality. X-ray examination of the chest showed some increased basal markings, and appreciable transverse enlargement of the heart involving both ventricles. Hb 12·5 g. per 100 ml. (85%). E.C.G. revealed left bundle-branch block and a small anterior myocardial infarct, but otherwise normal complexes and voltage.

Findings confirming thyroid deficiency included: on Jan. 31 plasma-cholesterol 316 mg. per 100 ml., plasma-proteins 8·4 g. per 100 ml. (albumin-globulin ratio 1 : 1), and protein-bound iodine under 1 γ per 100 ml. B.M.R. (Feb. 9) 14%. C.S.F. normal apart from protein 60 mg. per 100 ml. An intravenous insulin-tolerance test (Feb. 20) showed an abnormality consistent with myxœdema—*i.e.*, a slightly delayed fall and subsequent rise and no hypoglycæmic symptoms. The readings were as follows:

		Blood-sugar, mg. per 100 ml.
Fasting		99
Min. after glucose:	20	58
	30	51
	45	51
	60	68
	90	77
	120	87

A radioactive-iodine uptake test (Feb. 10) showed a very low urinary excretion—6% in 48 hours (4·1% in 0–8 hr., 0·8% in 8–24 hr., and 1·1% in 24–48 hr.)—and a high thyroid uptake (62% at 73 hours). This finding was inconsistent with spontaneous myxœdema and suggested previous long-continued administration of an antithyroid drug (fig. 3).

Thyroid biopsy on Feb. 14 (fig. 6) confirmed this indication, showing a hyperplastic gland made up of small and medium-sized follicles empty of colloid and lined by high cuboidal and columnar epithelium often showing papilliform infolding. There was moderate œdema of the interstitial tissue, which showed no lymphoid infiltration.

Progress.—From Feb. 7 to 20 the resorcinol ointment was not applied; and the patient noticed significant recession in the myxœdematous symptoms and features—a change also observed by us. The same ointment was then applied once more to her leg from Feb. 21 to March 13. On its subsequent withdrawal, improvement was again noticed, and her normal general health was restored without any medication (fig. 5B). Measurements of thyroid function during a further fortnight's application of the ointment and a further fortnight after withdrawal confirmed the antithyroid effects of applying this ointment to the ulcers.

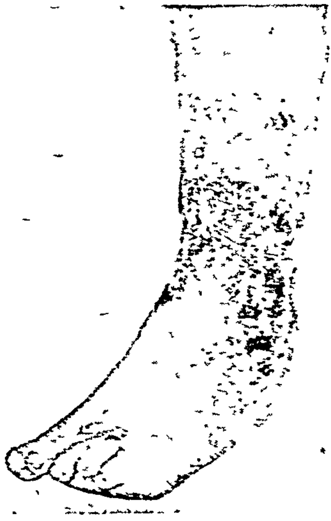

Fig. 6—Varicose leg ulcer in case 2.

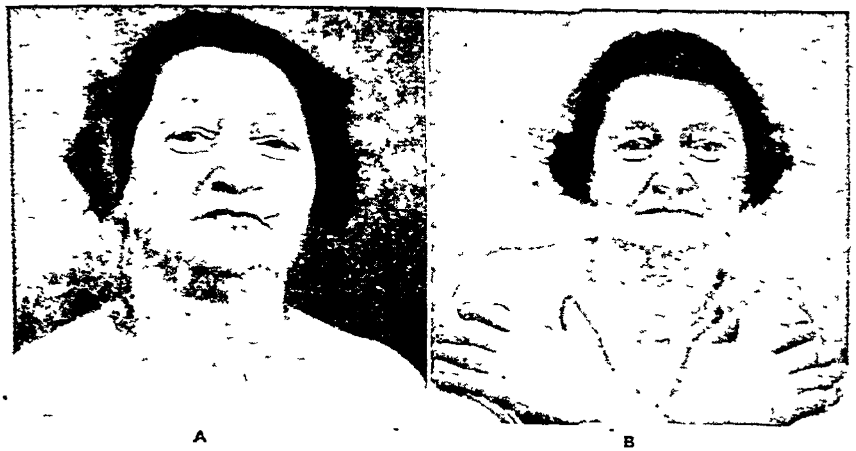
Case 3.—The patient, a housewife aged 50, with five children, was admitted to Fulham Hospital under the care of Dr. R. J. Harrison. For 2 years she had noticed increasing effort dyspnœa and sensitivity to cold, for 1 year general slowness and anergia; and for 7 months anorexia, irritable depression with poor memory and insomnia, husky voice, thinning of the scalp hair, and dry skin.

She had always had good health until 1943, when an attack of pneumonia was complicated by a left white-leg, which soon became complicated by a varicose ulcer which has never yet healed. For the past 3 years she had been applying to the ulcer ung. resorcini co. *B.P.C.* (4% resorcinol) using about 1 lb. per week. She had not been taking other drugs or unusual diet. For the last 2 years she had noticed swelling of the neck. She had also had two attacks of "jaundice"—one 3 years ago, lasting a month without pain or abnormal motions, and another 7 months ago lasting 4 months and associated at its onset with two weeks of vomiting and various pains; both attacks subsided spontaneously. Since the first attack she had been pale, depressed, and lethargic.



A B

Fig. 5—General appearance of case 2: (A) one week after last resorcinol application; (B)

goitre, just as in severe iodine deficiency. Only so long as the high blood-level of the thiocyanate is maintained is this hyperplastic gland prevented from concentrating iodine. When the thiocyanate administration is stopped, and the blood-thiocyanate concentration rapidly falls below the critical level, the unfettered hyperplastic gland takes up iodine avidly. When Rawson's patient was admitted for investigation the thiocyanate administration had been stopped, which explains the unexpectedly high iodine uptake which he found.

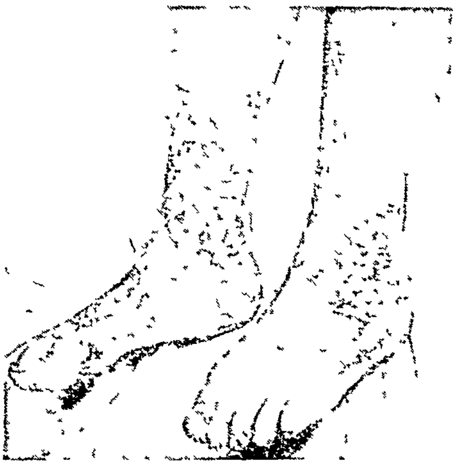


Fig. 1—Varicose leg ulcers in case 1.

Excessive uptake of iodine by the gland of a patient with myxœdema has therefore become the hallmark of myxœdema resulting from previous prolonged administration of an antithyroid agent. It was a similar finding with a radioactive iodine-uptake test in our patients which led ultimately to the conclusion that their myxœdema was due to resorcinol absorbed from the ointment applied to their varicose ulcers.

CASE-REPORTS

Case 1.—This patient, a 60-year-old housewife, had been under observation since 1936. At the age of 9 years she had had rheumatic fever; and in 1945 she was admitted with cardiac failure apparently consequent on mitral stenosis. Thereafter she was more or less continuously in some degree of heart-failure, from which she ultimately died in June, 1949.

The significant history relating to her myxœdema began in 1936 when she developed extensive bilateral ulceration of the legs after an injection for varicose veins. Despite Trendelenburg operations on both legs in 1945, these ulcers never healed. In October, 1948, she was admitted to hospital because of gross cardiac failure with extensive œdema.

Condition on admission.—Her weight was 14 st. 3 lb. (90 kg.), and she had large dirty ulcers on both legs (fig. 1). Certain features suggested that she might be mildly thyrotoxic. In addition to auricular fibrillation, which might have been due to the mitral stenosis, she had slight tremor of the hands, a warm periphery with sweating palms, and a blood-pressure of 150/60 mm. Hg. Neither thyroid enlargement nor abnormal eye signs were noted. The basal metabolic rate (B.M.R.) was + 25%, and the arm-to-tongue circulation-time (saccharin method) was 17 sec. An electrocardiograph (E.C.G.) showed normal voltage of the Q R S complex (fig. 2A).

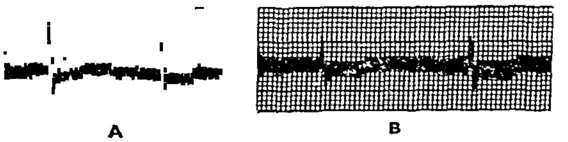

Fig. 2—E.C.G., lead 2, in case 1: (A) Oct. 2, 1948; (B) June 15, 1949.

Progress.—When seen again in the outpatient department in December, 1948, her condition appeared unchanged.

Readmission.—When the patient was readmitted on June 14, 1949, a striking change in her appearance was apparent. During the previous six weeks dyspnœa had increased considerably, and she had noticed a gain in weight. She had also noticed since the last admission a gradual increase in the size of her neck and gradually increasing dysphagia and hoarseness of voice. The only medication she had received since the previous admission was digitalis folia gr. 1 twice daily and applications of resorcinol ointment to the legs.

She now weighed 17 st. 10 lb. (112·5 kg.)—a gain of 49 lb. (22·3 kg.) in seven months. Her hair was coarse, her skin dry, and her general appearance myxœdematous. The thyroid gland was considerably and diffusely enlarged and firm, but neither nodular nor hard. She was in gross cardiac failure and her arm-to-tongue circulation-time was now 28 sec. The blood-pressure was 126/84 mm. Hg and an E.C.G. now showed low voltage and flat T waves (fig. 2B). The plasma-cholesterol was 192 mg. per 100 ml. and the protein-bound iodine under 1 γ per 100 ml. (normal 4–8 γ); the cerebrospinal fluid (C.S.F.) protein content was 100 mg. per 100 ml. A radioactive urinary iodine-excretion test (Arnott et al. 1949) on June 17 showed an extremely low excretion suggesting an avid uptake by the thyroid gland: 7·6% in 0–48 hr. (3% in 0–8 hr., 2·5% in 8–24 hr., and 2·1% in 24–48 hr.); and 2·3% in 48–72 hr. (fig. 3).

On the patient's admission to hospital, her legs were dressed with plain tulle gras, and the cardiac failure was treated with low-salt diet, rest in bed, and digitalis. For the first few days after admission her condition improved, but on June 26 her cardiac condition deteriorated and she died next day.

Necropsy confirmed the presence of rheumatic heart-disease with cardiac failure. The thyroid gland was about four times normal size (130 g.), and was pale and fleshy with a normal capsule. Histologically (fig. 4) the gland showed gross parenchymatous hyperplasia, with small and large follicles, mostly depleted of colloid, lined by columnar epithelium rich in papilliform infoldings. There were occasional islets, a few millimetres across, of hyperplastic follicles filled with peripherally vacuolated colloid. The gland was traversed by numerous thickened fibrous trabeculæ. It showed very occasional scattered lymphocytes but no lymphoid follicles, strongly suggesting that the hyperplasia was a response to a goitrogen rather than thyrotoxicosis.

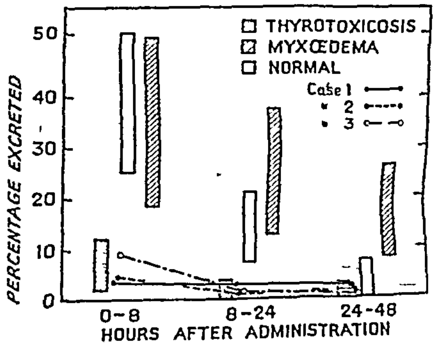

Fig. 3—Urinary excretion of radioactive iodine from each of the 3 patients, compared with the range of findings (mean, S.D. ± 2) in 30 normals, 35 obvious thyrotoxic patients, and 10 patients with typical spontaneous myxœdema.

Case 2.—A normally active housewife, aged 59 years, who was the mother of seven children, attended the outpatient department on Jan. 31, 1950, complaining of a series of symptoms which she insisted had all developed over the last two months. For two months she had noticed tiredness with backache, for six weeks tinnitus and deafness, for four weeks dyspnœa with substernal anginal pain on effort, and for two weeks anorexia, unusual sensitivity to cold, puffiness and dry scaliness of the face and arms, hoarseness, and slight cough without sputum.

Previously she had had a normal menopause at the age of 49, and had always had good general health except for varicose veins and ulcers on both legs. For 12 years she had been liable to evening swelling of the legs. She had never previously sought a doctor's advice, although for 23 years the leg ulcers had never healed. For the past 2 years she had been dressing these with a chemist's ointment three times daily, using approximately 4–6 oz. per week; this was ascertained to be 12% resorcinol in glycerin, paraffin, and lanoline. She had taken no other medicines, and her diet was not abnormal.

Examination.—The patient had a typical myxœdematous appearance (fig. 5 A). Her weight, usually about 10 st., was 11st. 11 lb. (75 kg.). She was moderately obese with supraclavicular pads and a rather prominent abdomen. Her

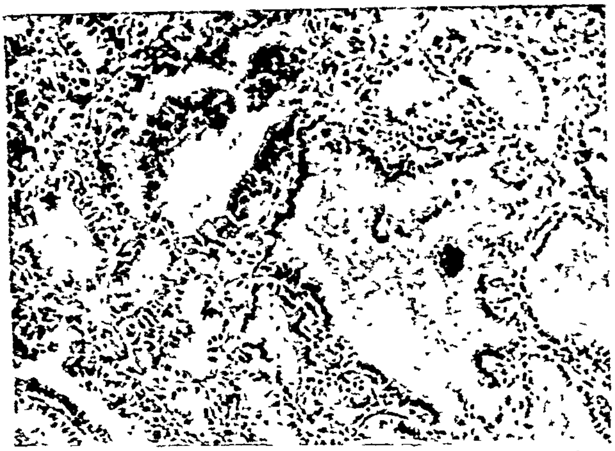

Fig. 4—Section of thyroid gland (× 90) post mortem in case 1.

face and eyes were puffy and her features heavy; her hair was dry, and her skin, especially on the face, arms, knees, and feet, dry and scaly; her palms and soles were grossly hyperkeratotic. All these features, she insisted, were recent. Her nails were normal.

The pulse-rate was 72 per min., and blood-pressure 110/80 mm. Hg. The jugular venous pressure was not raised; the apex-beat was $4\frac{1}{2}$ in. from the midline in the 5th intercostal space; and the heart sounds were normal. She showed moderate kyphoscoliosis, a few crepitations at the base of the right lung, and a few generalised rhonchi. Palpation of the neck revealed a very soft, diffusely enlarged thyroid gland, with to-and-fro audible bruits; its weight was estimated at 100 g. Its size and its vascularity were later confirmed both by I^{131} measurement and by biopsy inspection. Moderate œdema was evident in both legs, but not elsewhere; over most of the circumference of the left leg just above the ankle was a very large, grossly purulent ulcer. A similar, smaller ulcer was present just above the right external malleolus (fig. 6).

Investigations.—The patient was admitted for investigation on Feb. 7, 1950, when the ointment application was stopped. Urine: no abnormality. X-ray examination of the chest showed some increased basal markings, and appreciable transverse enlargement of the heart involving both ventricles. Hb 12·5 g. per 100 ml. (85%). E.C.G. revealed left bundle-branch block and a small anterior myocardial infarct, but otherwise normal complexes and voltage.

Findings confirming thyroid deficiency included: on Jan. 31 plasma-cholesterol 316 mg. per 100 ml., plasma-proteins 8·4 g. per 100 ml. (albumin-globulin ratio 1 : 1), and protein-bound iodine under 1 γ per 100 ml. B.M.R. (Feb. 9) 14%. C.S.F. normal apart from protein 60 mg. per 100 ml. An intravenous insulin-tolerance test (Feb. 20) showed an abnormality consistent with myxœdema—i.e., a slightly delayed fall and subsequent rise and no hypoglycæmic symptoms. The readings were as follows:

		Blood-sugar, mg. per 100 ml.
Fasting		99
Min. after glucose:	20	58
	30	51
	45	51
	60	68
	90	77
	120	87

A radioactive-iodine uptake test (Feb. 10) showed a very low urinary excretion—6% in 48 hours (4·1% in 0–8 hr., 0·8% in 8–24 hr., and 1·1% in 24–48 hr.)—and a high thyroid uptake (62% at 73 hours). This finding was inconsistent with spontaneous myxœdema and suggested previous long-continued administration of an antithyroid drug (fig. 3).

Thyroid biopsy on Feb. 14 (fig. 6) confirmed this indication, showing a hyperplastic gland made up of small and medium-sized follicles empty of colloid and lined by high cuboidal and columnar epithelium often showing papilliform infolding. There was moderate œdema of the interstitial tissue, which showed no lymphoid infiltration.

Progress.—From Feb. 7 to 20 the resorcinol ointment was not applied; and the patient noticed significant recession in the myxœdematous symptoms and features—a change also observed by us. The same ointment was then applied once more to her leg from Feb. 21 to March 13. On its subsequent withdrawal, improvement was again noticed, and her normal general health was restored without any medication (fig. 5B). Measurements of thyroid function during a further fortnight's application of the ointment and a further fortnight after withdrawal confirmed the antithyroid effects of applying this ointment to the ulcers.

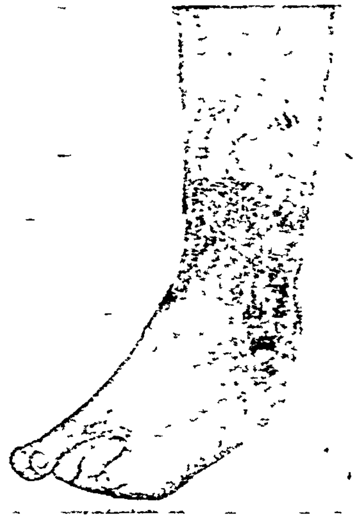

Fig. 6—Varicose leg ulcer in case 2.

Case 3.—The patient, a housewife aged 50, with five children, was admitted to Fulham Hospital under the care of Dr. R. J. Harrison. For 2 years she had noticed increasing effort dyspnœa and sensitivity to cold, for 1 year general slowness and anergia; and for 7 months anorexia, irritable depression with poor memory and insomnia, husky voice, thinning of the scalp hair, and dry skin.

She had always had good health until 1943, when an attack of pneumonia was complicated by a left white-leg, which soon became complicated by a varicose ulcer which has never yet healed. For the past 3 years she had been applying to the ulcer ung. resorcini co. *B.P.C.* (4% resorcinol) using about 1 lb. per week. She had not been taking other drugs or unusual diet. For the last 2 years she had noticed swelling of the neck. She had also had two attacks of "jaundice"—one 3 years ago, lasting a month without pain or abnormal motions, and another 7 months ago lasting 4 months and associated at its onset with two weeks of vomiting and various pains; both attacks subsided spontaneously. Since the first attack she had been pale, depressed, and lethargic. For the first fortnight of the second, she also suffered

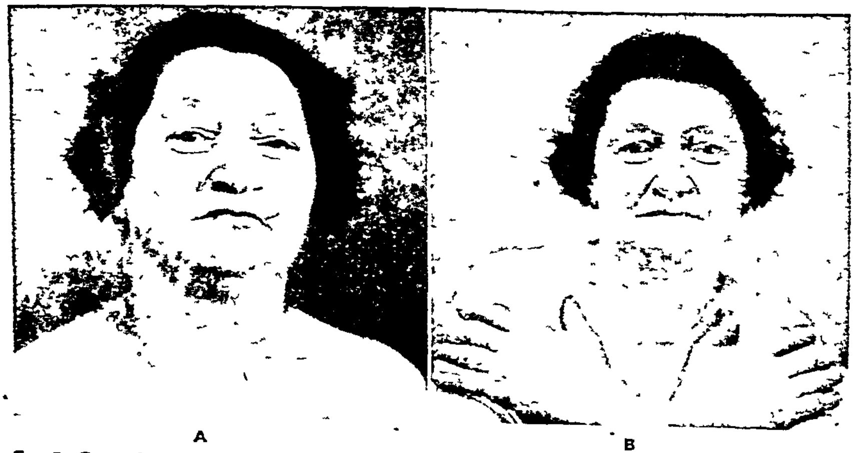

Fig. 5—General appearance of case 2: (A) one week after last resorcinol application; (B) on discharge from hospital, 35 days after finally ceasing resorcinol application.

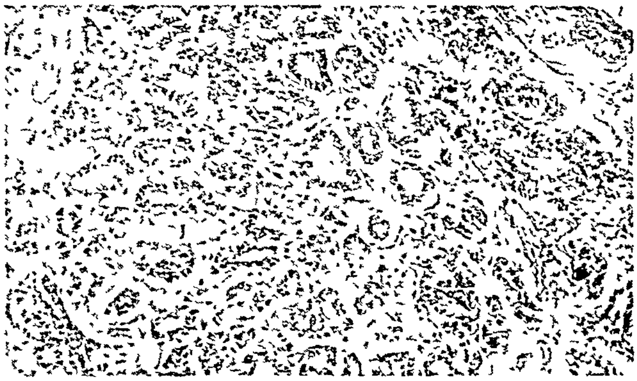

Fig. 7—Thyroid biopsy in case 2. (× 90.)

from vomiting, left-sided upper abdominal pain radiating round the left side of the chest, diplopia, and pain, numbness, and tingling in both hands and in the left leg. Complete amenorrhœa, probably menopausal, supervened 7 months before admission, after 2 years of irregular periods.

Examination.—The patient, when examined on Jan. 16, 1950, was found to be a placid, pale obese woman weighing 11 st. (70 kg.). She had been obese for many years and 3 years ago weighed 13 st. She had supraclavicular pads, and the skin was dry and scaly, especially on the face and arms; the palms of the hands were horny, and the scalp hair thin and dry. Pulse-rate 68 per min., regular; blood-pressure 180/100 mm. Hg. The thyroid gland was diffusely enlarged (estimated at over 100 g.), soft, without nodules, and with audible bruits. She had moderate kyphosis. Above the left ankle were two varicose ulcers about 2 in. and 3 in. in diameter. No other significant abnormalities were noted.

Investigation.—B.M.R. − 28% and − 18%. Plasma-cholesterol 151 mg. per 100 ml. Blood-urea 31 mg. per 100 ml. E.C.G.: low-voltage curve. Hb 6·8 g. per 100 ml. (red blood-cells, 3,800,000 per c.mm., packed-cell volume 35%, mean corpuscular volume 92 c.μ, mean corpuscular hæmoglobin concentration 25%). Wassermann and Kahn reactions negative. Liver-function tests normal (serum-bilirubin 0·2 mg. per 100 ml., thymol-turbidity test 2 units, serum colloidal-gold reaction negative, serum alkaline phosphatase 6·3 units per 100 ml.). Fractional test-meal: normal free and total acidity. Urea-clearance 63% of normal. Plasma protein-bound iodine was not estimated until 7 weeks after discontinuing resorcinol ointment; it was then normal—4·9 γ per 100 ml.

A radioactive-iodine uptake test (Feb. 14) showed a very low urinary excretion: 9·9% in 48 hours (8·8% in 0–8 hr., 0·8% in 8–24 hr., and 0·3% in 24–48 hr.) (fig. 3). This again suggested, in association with the signs of myxœdema, previous administration of an antithyroid drug over a long period.

A biopsy of her thyroid gland was taken on Feb. 24, 5 weeks after the ointment was stopped. The histology was that of a hyperplastic gland, made up of small and large follicles lined by a high cuboidal and low columnar epithelium often thrown into papilliform infoldings. The majority of the follicles contained colloid, mostly showing peripheral vacuolation. There was moderate œdema of the interstitial tissue, which contained only very occasional scattered lymphocytes. The colloid accumulation suggested a phase of recovery in a goitrogen-induced hyperplasia (fig. 8).

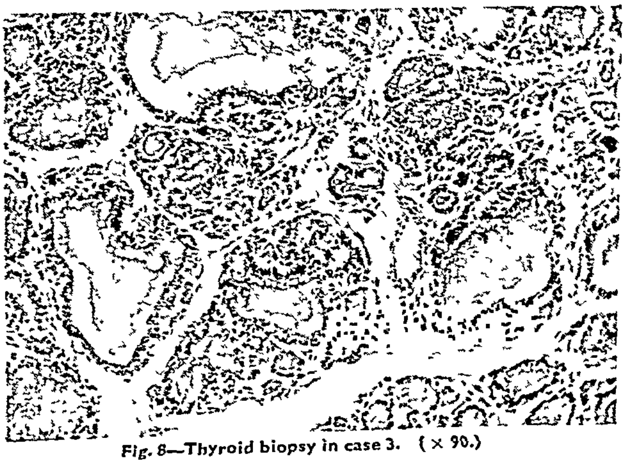

Fig. 8—Thyroid biopsy in case 3. (× 90.)

Progress.—The resorcinol ointment was discontinued from Jan. 16 to Feb. 20, by which time both the patient and her attendants had noted considerable improvement in her symptoms—the lethargy and depression had lessened, the skin was warmer and softer, and the anæmia had begun to improve (Hb 10·4 g. per 100 ml. on Feb. 17).

DISCUSSION

There is little room for doubt that these three patients had myxœdema. The clinical picture was typical (see figs. 5 and 8). In all three there was a low basal metabolic rate, and in the two patients tested before the withdrawal of the ointment protein-bound iodine in the blood was low. In cases 1 and 2 the C.S.F. protein content was high, and in cases 1 and 3 the electrocardiographic findings were consistent with the diagnosis; the absence of electrocardiographic change in case 2 was probably due to the short duration of the myxœdema. Histological examination of the skin in cases 1 and 2 showed an appearance consistent with the diagnosis of myxœdema.

A striking feature in these cases was the rapid development of severe myxœdematous symptoms and signs; in cases 1 and 2 the patients were able to date the onset to within a few weeks. Spontaneous myxœdema usually develops so slowly that it is difficult to define the onset within a period of years; and sometimes the slow change remains unobserved by either the patient or his relatives. This rapid development of myxœdema in itself suggested an unusual cause, and prompted a very careful but unsuccessful search for exposure to known antithyroid agents. However, the rapid onset, with goitre showing histological features of hyperactivity, very strongly suggested that an antithyroid drug was responsible. The excessive radio-iodine uptake by the thyroid glands of these myxœdematous patients (fig. 3) confirmed this suspicion. Since all three patients had applied resorcinol ointment to their leg ulcers, it seemed possible that this was the agent causing the myxœdema.

It is probably significant that all their leg ulcers were large (figs. 1 and 6) and that the ointment had been applied for a long time. The suspicion that resorcinol was indeed responsible was strengthened by the finding in all three cases that when resorincol applications were stopped, the thyroid took up iodine avidly; and in cases 2 and 3 the myxœdematous features rapidly disappeared with a return to normal levels of the basal metabolic rate and serum protein-bound iodine. In case 1 the rapid worsening of the cardiac condition on the 12th day after stopping the resorcinol applications may have been due to a similar release of thyroid hormone. Furthermore, in case 2 a later reapplication of resorcinol to the leg ulcer grossly reduced the thyroid's ability to concentrate I^{131} and again lowered the serum protein-bound iodine to levels found in myxœdema. Finally, subsequent biological studies with resorcinol have confirmed its antithyroid activity in animals, provided it is administered parenterally (Doniach and Fraser 1950).

One feature generally found as a sign of thyroid deficiency—a high serum-cholesterol—was absent from two of these patients and little evident in the third (case 2, 316 mg. per 100 ml.). However, this is not a universal finding in thyroid deficiency; it is only a secondary effect, whose mechanism is ill understood (Peters and Man 1943). In thyroidectomised animals the raised cholesterol can be abolished by dietetic restriction (Entenman et al. 1942). It may be absent from cases of thyroid deficiency associated with liver disease or malnutrition—e.g., from the severer cases of Simmonds's disease with thyroid deficiency, or from cases of severe primary malnutrition which show other evidence of thyroid deficiency. It is probably relevant that of our two patients with serum-cholesterol levels in the normal range, one (case 1) had had long-standing severe heart-failure due to rheumatic heart-disease, and the other (case 3) was anæmic. Further, resorcinol, which, like phenol, is known to be metabolised by the liver—i.e., conjugated and then excreted in the urine—may be similarly toxic to the liver. Some such toxic effect may possibly have contributed to the failure of the cholesterol levels to rise with thyroid deficiency. Since resorcinol is known to produce methæmoglobinæmia, its toxic effects may also have caused the anæmia and the other complicating symptoms found in case 3. Further studies are still being conducted with the collaboration of our colleagues on two of these three patients, and fuller details will be published later.

Many antithyroid compounds are already known (Astwood et al. 1945). The study by Chesney et al. (1928) of the goitrogenic or antithyroid action of cabbage probably initiated the investigation of such compounds. Marine et al. (1932) afterwards showed that the goitrogenic agent in cabbage is probably a glucosidic compound of an organic cyanide. Later discoveries of clinically important antithyroid agents included those of rape seeds by Hercus and Purves (1936), of sulphonamides by Mackenzie et al. (1941), and of thiouracil by Astwood (1943); and many subsequent studies have expanded these discoveries. Griesbach et al. (1941) showed that the goitrogenic action of these drugs was mediated through secondary stimulation of the anterior pituitary, arising from the interruption of thyroid-hormone secretion. The known antithyroid drugs can be grouped into three main chemical types (Charipper and Gordon 1947): (1) the thiourelene compounds, characterised by the thiocarbonamide grouping ($> N - CS - N <$), which include thiourea, thiouracil, and ergothionene; (2) the anilene derivatives, characterised by the amino-benzene grouping and including the sulphonamides, and aminobenzenes such as 4.4′ diaminodiphenylmethane; and (3) the thiocyanates and the organic cyanides. Chemically, resorcin, or resorcinol, a dihydroxyphenol, , is not clearly allied to any of the former groups, but some of its known chemical features may be relevant to its antithyroid action. It can be iodinated either by free iodine, or by iodides in the presence of an oxidising agent, to form tri-iodoresorcinol. Its formula somewhat resembles that of tyrosine,  $CH_2CHNH_2.COOH$, which is believed to be the precursor which the thyroid gland iodinates by some oxidising mechanism, in the presence of iodide, to form thyroxine and the thyroid hormone. The antithyroid action of resorcinol may be due to its competing in the thyroid gland with tyrosine for the iodinating mechanism; or to some other toxic action. Further investigation is in progress on the biological action of resorcinol and allied substances.

SUMMARY

In three cases myxœdema was associated with varicose ulcers to which resorcinol ointment had been applied.

Further study showed that the thyroid glands of these patients were enlarged and hyperactive.

On withdrawing resorcinol, the myxœdema subsided and thyroid function returned to normal.

Resorcinol, when absorbed through a leg ulcer, is an antithyroid agent.

We wish to acknowledge an indebtedness to many colleagues for help with these studies: to Mr. Maurice R. Ewing and Mr. Selwyn Taylor for biopsies; to Dr. I. Doniach for the histological studies; to Dr. Q. J. G. Hobson, aided by Dr. L. Phillips and Dr. M. Jones, for extensive assistance in the clinical studies; to Mr. D. G. Arnott, B.SC., and to Mr. F. S. Stewart (Medical Research Council radiotherapeutic unit) for the isotope measurements; to Miss P. Scarlett for the iodine estimations; and to Mr. V. Wilmott for the photographs. We are also especially indebted to Dr. R. J. Harrison for bringing case 3 to our notice, and for his generous courtesy in transferring her to our care for a period of investigation.

EFFECT OF RESORCINOL ON THE THYROID UPTAKE OF I^{131} IN RATS

I. DONIACH
M.D. Lond.

RUSSELL FRASER
M.D. N.Z., F.R.C.P., D.P.M.

From the Postgraduate Medical School of London

IN three elderly women with myxœdema and a goitre, Bull and Fraser (1950) found that the thyroid disorder was due to prolonged application of a resorcinol ointment to varicose ulcers. Radio-iodine uptake studies confirmed the suspicion that the resorcinol applied to these ulcers had an antithyroid action and suggested the need for further study of this antithyroid action.

We report here preliminary results of some experiments on the effect of resorcinol on thyroid function in the rat.

METHODS

Adult rats, weighing 150–250 g., mostly females of the hooded Lister strain, were used throughout.

The ability of the rats' thyroids to take up iodine was measured by killing them 1, $1^1/_2$, and 2 hr. after an intraperitoneal injection of 10 microcuries (μC) I^{131} with 0·5 μg. carrier potassium iodide, and counting the radioactivity in the alkaline digest of the dissected thyroid glands in a liquid counter (Veall 1948). For autoradiographs, rats were killed 2 hr. after an intraperitoneal injection of 18 μC of I^{131}.

Drugs whose antithyroid effect was being tested were injected subcutaneously in 1 ml. of water, 10–30 min. before administration of I^{131}, the injection sometimes being repeated 1 hr. later. The effect of these drugs was assessed either by measuring the reduction in the thyroid uptake from that found in the controls, or by making an autoradiograph instead of the digest.

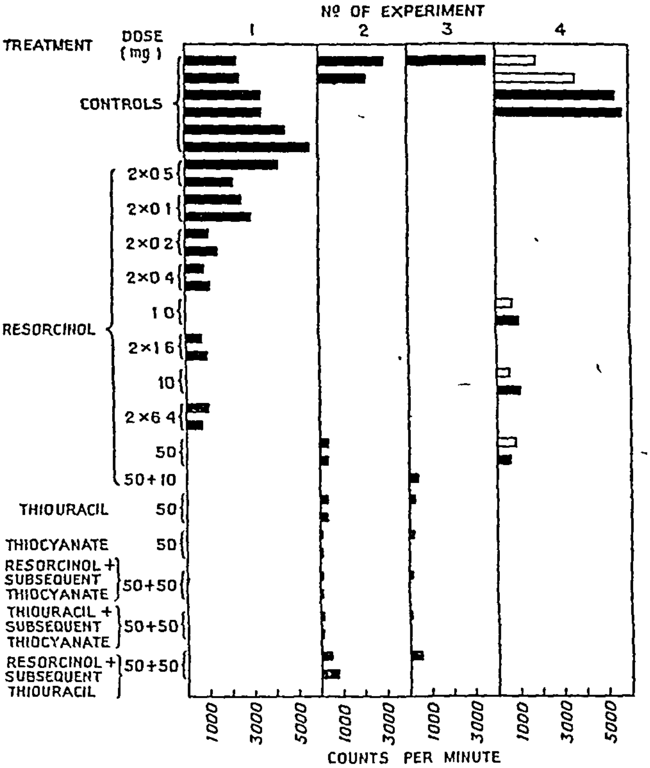
The drugs used were: 4-methyl-2-thiouracil, as a watery suspension of crystals containing at least 50 mg. per ml., to ensure maximal antithyroid effect; sodium thiocyanate, 50 mg. per ml.; and resorcinol in graded doses or given in the drinking-water as a 2% solution. In the accompanying figure, the thyroid uptake of each rat is recorded simply as the actual number of counts per min. given by the thyroidal digest,* and the results are summarised.

RESULTS

Previous injection with 1 mg. (5 mg. per kg. body-weight) or more of resorcinol reduced the iodine uptake

---

* The results are presented by this method because of the wide range of readings among the controls and the small number of rats used per experiment. The reader should compare the uptake of any rat only with that of the controls or others recorded in the same experiment. The ratio of uptake by treated rats to their own controls is comparable in all experiments.



Inhibiting effect of resorcinol on uptake of I^{131} by rats' thyroids, compared with that of methyl thiouracil and sodium thiocyanate.

Each rat is represented by a horizontal bar whose length gives the counts per min, recorded from its digested thyroid. The rats were killed 2 hr. after injection of 10 µC I^{131}, except all rats in experiment 3, which were killed $1^1/_2$ hr. afterwards, and those shown as open bars in experiment 4, which were killed 1 hr. afterwards.

to $^1/_5$–$^1/_9$ of that found in controls—an extent not exceeded with higher doses and comparable to the maximal reduction obtained with methyl thiouracil. Further experiments will be needed to establish the minimum dose required to produce the maximal antithyroid effect. A number of rats were given the resorcinol in two doses—the second, 1 hr. 10 min. before they were killed. As is shown in the figure, the results did not differ greatly from those produced by single doses. When the resorcinol was administered orally instead of parenterally, there was an indication in some animals of a smaller, but definite, antithyroid effect, which will be further studied.

Comparison of the antithyroid action of resorcinol with that of other known drugs throws some light on its mode of action on the thyroid. The thyroid is known to concentrate iodide from the serum in at least two steps—first by concentrating the iodide in the gland, and then by organic binding of this iodide into protein, in which form most of the thyroid's store is made. The first step is inhibited by thiocyanate and the second step by the thiouracils; in each case this is the only known antithyroid effect of the drug. Autoradiographs of alcohol-fixed paraffin-embedded thyroids show the presence of organically bound iodine only. Autoradiographs made after pretreatment with resorcinol, as after methyl thiouracil, failed to show any organically bound I^{131}. The prevention of organic binding was further confirmed by finding that the antithyroid action of resorcinol could be further enhanced by injecting sodium thiocyanate 1 hr. before killing; and the antithyroid action of methyl thiouracil could be enhanced in exactly the same way (see figure, experiments 2 and 3). This addition of thiocyanate further reduced the concentration of I^{131} from $^1/_5$ to $^1/_{10}$ of that obtained with resorcinol or methyl thiouracil alone. In this connection, it should be noted from experiment 4 that the thyroid uptake in the presence of resorcinol at the end of 1 hr. is not significantly different from that at the end of 2 hr.; thus the addition of thiocyanate at 1 hr. before killing had evidently discharged some of the iodide ion which had been concentrated there despite the presence of resorcinol. Vanderlaan and Vanderlaan (1947) have reported similar results with propyl thiouracil and thiocyanate. From the figure (experiments 2 and 3) it will also be noted that when thiouracil is given in addition to resorcinol antithyroid action was not enhanced.

With regard to the toxicity of resorcinol, 50 mg. doses never proved fatal, but the injected animals all showed a severe tremor for the first half-hour. Smaller doses had no overt toxic results.

CONCLUSIONS

Preliminary assessment of the antithyroid action of resorcinol on rats, using I^{131} to measure thyroid uptake, shows it to be similar to that of methyl thiouracil in all the respects tested—namely, the maximal depression of thyroid uptake of iodine which can be induced, the abolition of organic binding as evidenced by autoradiography, and the enhancement of its antithyroid effect obtainable by the additional injection of thiocyanate but not of methyl thiouracil.

We are indebted to Mr. D. G. Arnott, B.SC., for the isotope measurements and help in the experiments, and to Mr. S. R. Pelc, PH.D., for the autoradiographs.

SEROLOGICAL DIAGNOSIS OF HERPES SIMPLEX INFECTIONS

MARGARET E. HAYWARD *
B.Sc. Melb.

From the Department of Bacteriology, University of Liverpool

PRIMARY infection with herpes simplex virus occurs frequently in young children (Dodd et al. 1938, Burnet and Williams 1939). The primary infection may be symptomless (Anderson and Hamilton 1949) or there may be clinical manifestations varying from inconspicuous vesicular lesions about the mouth, with or without stomatitis, to more extensive eruptions on the skin of other parts of the body, especially in children or adults suffering from chronic eczema. The acute stomatitis (aphthous stomatitis) may be accompanied by constitutional upset (McNair Scott et al. 1941). Cases of herpetic meningo-encephalitis may also be commoner than the literature suggests. Infected individuals apparently carry the virus throughout life and their sera contain antibodies to the virus.

The diagnosis of herpetic infection may be confirmed or established by isolation of virus or by demonstrating an increase in antibody in the serum during the illness. Estimation of serum antibody has generally been made by testing the power of the serum to inhibit the action of the virus in susceptible animals or to prevent the development of lesions on the chorioallantois of developing chick embryos (neutralisation test). Such methods require several days for their performance and a sensitive in-vitro serological test would offer obvious advantages. Sera containing antibodies to herpes virus were shown by Bedson and Bland (1929) to fix complement in the presence of a herpetic antigen; their technique when used in the examination of human sera (Brain 1932) did not give as high a proportion of positive reactions in adults as did the neutralisation test in the hands of other workers (Andrewes and Carmichael 1930, Burnet and Williams 1939).

* Complement-fixation titres are expressed as reciprocal of highest dilution of serum giving < 50% hæmolysis.

Observations on a complement-fixation test for the detection of antibody to the virus of herpes simplex were reported in a previous paper (Hayward 1949). The antigen for these tests was prepared from herpes-infected extra-embryonic fluids from developing chick embryos several days after inoculation of virus into the yolk-sac, into the amniotic cavity, or into the allantoic cavity. The activity of the antigen was found to be due chiefly to a "soluble" specific substance separable from the virus by high-speed centrifugation; the antigen was stable on storage at 4°C but its activity was considerably weakened by heating at 56°C for 1 hour. Serological differences were not detected among four recently isolated strains of herpes simplex virus by the complement-fixation technique using immune sera prepared in guineapigs and sera from individuals who provided three of the strains. Infected chick-embryo fluids were more sensitive antigens than extracts of tissue from infected animals, and a preliminary examination of human sera by this complement-fixation test gave a high proportion of positive reactions.

Before accepting this technique as a sensitive method for the detection of herpetic antibody in human sera, it seemed advisable to find out whether it gave results comparable to those obtained by neutralisation tests which are commonly used by other workers for this purpose. Immune guineapig sera prepared against four strains of virus were therefore tested against each of the strains by both complement-fixation and neutralisation techniques. A similar comparison was made of 95 specimens of sera from healthy adults. The results of these tests are reported in this paper.

METHODS

The virus strains studied, the preparation of the antigen and the technique of the complement-fixation tests have already been described (Hayward 1949). To obtain potent antigen, the fluids from individual eggs were tested separately in doubling dilutions against an immune human serum diluted 1 in 8. Only those fluids which showed fixation in high dilution (1 in 64 or 1 in 128) were pooled and used for routine tests.

The guineapig immune sera, as previously described, were obtained from animals which had received several injections of active virus from herpes-infected guineapig pads. The 95 specimens of human serum were kindly supplied by Dr. D. Lehane, director of the Liverpool Regional Blood Transfusion Service. When testing these sera, known negative and positive control sera were included with each batch.

The neutralisation tests were carried out by the chorio-allantois titration technique, 4 membranes being inoculated with each serum-virus mixture. All the sera were inactivated at 56°C for 20 minutes before the test. The guineapig sera were tested in dilutions of 1 in 10, 1 in 100, and 1 in 1000, the human sera in a dilution of 1 in 10 only. Serum from a normal uninoculated guineapig and sera from individuals with no history of herpetic infection were used as control negative sera. Herpes-infected allantoic and amniotic fluids collected as for complement-fixation tests served as a source of virus for the neutralisation tests. After clarification by low-speed centrifugation the virus content of the fluids was estimated by titration on the chorioallantois of 12-day chick embryos. For tests with sera a dilution of the virus was used which gave a count of over 1000 lesions on control membranes. The serum dilutions were mixed with equal volumes of virus suspension and the mixtures were allowed to stand for 1–2 hours at room-temperature before inoculation of 0·2 ml. volumes on the chorioallantois of 12-day chick embryos. After two day's incubation, the membranes were cut out and placed in 2% formol saline and the number of lesions counted. The results were expressed as the percentage reduction in the number of lesions compared with those on membranes which had received the control mixtures of virus and diluted negative serum.

RESULTS

Titration of antibody in immune guineapig sera by complement-fixation and neutralisation tests.—Table I shows the results when the immune guineapig sera were tested against each of the four viruses both by complement-fixation and neutralisation techniques. With the complement-fixation technique the sera are arranged in fixing potency in order P<H<McC<N. This order is maintained in tests with antigens from all four viruses as mentioned in the previous paper.

Similarly when the sera were tested by the neutralisation technique, the relative titre of antibody was of the same order except that serum P gave better neutralisation of virus H than did the homologous serum H.

These results support the opinion based on complement-fixation tests only (Hayward 1949) that there are no marked antigenic differences between the four virus strains. The titre of antibody measured by the complement-fixation technique parallels that demonstrated by neutralisation tests; there is no evidence that different antibodies are measured by the two techniques.

Comparison of complement-fixation and neutralisation with human sera.—The results of the complement-fixation and neutralisation tests with the 95 human sera are shown in table II.

In neutralisation tests each serum was tested in a single dilution of 1 in 10. Those sera which contained antibody showed 95–100 % neutralisation, and sera with weaker neutralising capacity were not observed, though the high lesion counts on the control membranes did not

TABLE II—HERPETIC ANTIBODY IN 95 HUMAN SERA DETERMINED BY COMPLEMENT-FIXATION AND NEUTRALISATION

Neutralisation		Complement-fixation					
		Negative at serum dilution 1/8	Positive at final serum dilution of				
			1/8	1/16	1/32	1/64	1/128
–	19	19	0	0	0	0	0
+	76	1	9	12	37	12	5
Totals	95	20	75				

facilitate the detection of such sera. The all-or-nothing character of herpes-neutralising antibody in adult human sera is, however, generally recognised (Burnet 1946). The testing of a single serum dilution did not enable a quantitative estimate of the amount of antibody present in individual sera to be made.

It can be seen that 75 sera (80%) gave a positive test and 19 (20%) gave a negative test for herpetic antibody by both techniques. One serum gave a positive result by neutralisation and was negative by complement-fixation. Unfortunately this specimen was too small to allow the test to be repeated.

These tests with human sera, like those with the guineapig sera, show close agreement by the two techniques. The proportion of sera showing herpetic antibody (80%) is similar to that found by others (Burnet and Lush 1939).

SUMMARY

Immune guineapig sera for four strains of herpes simplex virus were tested for antibody against the four strains by complement-fixation and neutralisation techniques. The results by the two techniques showed close agreement and did not disclose antigenic differences among the four virus strains.

Tests on 95 adult human sera by the two methods gave similar findings with the two techniques. 80% of these sera contained herpetic antibody.

The complement-fixation technique, using as antigen extra embryonic fluids from herpes-infected chick embryos, provides a simple and reliable test for the detection and titration of herpetic antibody in human sera.

I am indebted to Prof. A. W. Downie for encouragement and advice during the course of this work.

TYPHOID FEVER TREATED WITH CHLORAMPHENICOL

DEVELOPMENT OF THE CARRIER STATE

A. D. M. DOUGLAS
M.B. St. And., D.P.H., D.P.M.
SENIOR PSYCHIATRIC REGISTRAR, SAXONDALE HOSPITAL, NOTTINGHAM

SEVERAL papers published in England in the last few months have confirmed the original observation, made by Prof. J. E. Smadel and his team in Malaya, of the value of chloramphenicol in typhoid fever. So far, however, the drug has not prevented the development of relapses or of the chronic carrier state. At a meeting of the epidemiological section of the Royal Society of Medicine on March 17 the hope was expressed[1] that "some cunning and at present unsuspected technique" would make it possible to prevent and cure the carrier state with chloramphenicol. How much cunning is likely to be required is indicated by the following 3 cases treated with chloramphenicol, of which 2 have become chronic carriers.

CASE-RECORDS

Case 1.—A female catatonic schizophrenic, aged 37, was treated with chloramphenicol from the third day of her illness, when cultures of the blood and the stools grew *S. typhi phage-type* F1. She was given 4 g. in the first hour, 0·25 g. two-hourly for the next four days, then 0·75 g. twice daily for nine days, and finally one dose of 0·75 g., making a total of 31 g. Because there was clinical evidence of bronchopneumonia she was also given 3,650,000 units of penicillin and 36 g. of 'Sulphatriad' in six days. On the third day of chloramphenicol treatment her temperature fell sharply, and it swung at a lower level until four days later, when, to all intents, the patient's illness seemed to have resolved.

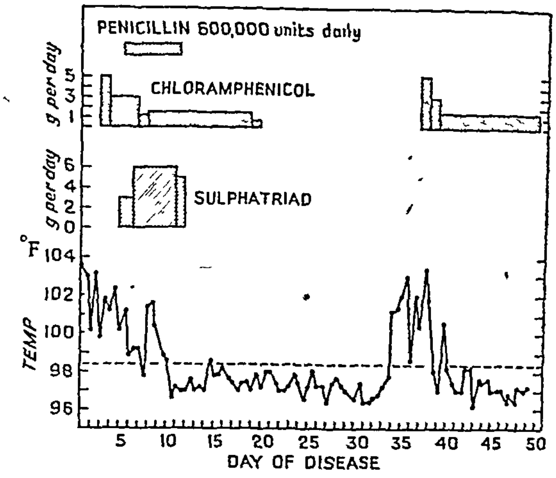

Fig. 1—Case 1. Relapse in typhoid fever despite apparently good response to chloramphenicol.

Relapse.—Sixteen days after the withdrawal of chloramphenicol the patient relapsed. Blood-culture and stools were again positive for *S. typhi*. On the fourth day of this relapse chloramphenicol was started again, and she received a total of 24·75 g. in thirteen days. Her temperature again settled after three days (fig. 1). Her excreta became negative for *S. typhi* after four days and have remained so for the subsequent five months. Clinically, the relapse was characterised by what appeared to be neurological involvement. She had a well-marked "trombone" tremor of the tongue and a coarse tremor of the lips, arms, and legs, but no other neurological abnormalities were detected. These symptoms appeared on the third day of her relapse and had disappeared forty-eight hours after the reintroduction of chloramphenicol. Thereafter the patient made an uneventful recovery.

Case 2.—A female schizophrenic, aged 34, was at first diagnosed as having bronchopneumonia, so penicillin and sulphatriad were given at once. Three days later a blood-culture grew *S. typhi* F1. Chloramphenicol was started next

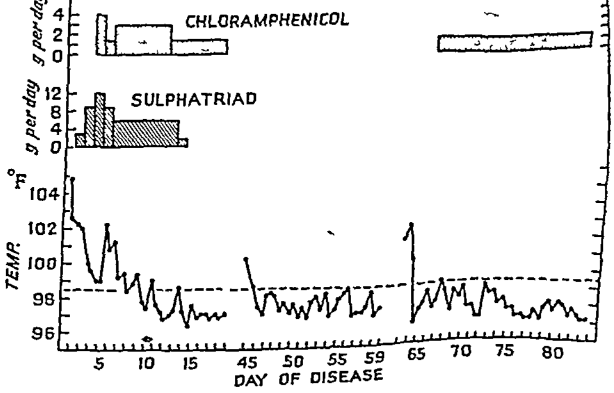

Fig. 2—Case 2. Response in patient who became a chronic carrier.

---

1. See *Lancet*, March 25, p. 544.

day, the fourth day of her illness, 4 g. being given initially, and then 1·5 g. on the second day, 3 g. daily for six days, and finally 1·5 g. daily for six days; the total amount was 32·5 g. in fourteen days, and in the same period she received 7,900,000 units of penicillin and 77 g. of sulphatriad. She seemed to recover completely from her severe attack of typhoid (fig. 2), though in the early days of her convalescence cultures from both urine and fæces occasionally yielded *S. typhi*.

On the forty-fifth day of her illness her temperature rose to 100·2°F, but bacteriological and serological examinations for *S. typhi* were negative.

On the sixty-third day the patient had a mild rigor, with a temperature of 102 0°F. Blood-culture was negative, but since both urine and fæces grew *S. typhi* it was thought that this might be a relapse, so she was given a further course of chloramphenicol: 1·5 g. daily for seventeen days to a total of 25·5 g. On the day after her rigor she complained of tenderness over the gall-bladder, her urine contained bile-salts and bile-pigments in excess, and she then showed clinical jaundice, making a relapse seem doubtful, but it was decided to continue with the chloramphenicol. Her skin and conjunctivæ cleared during this course. Five days after the chloramphenicol was stopped her urine again yielded *S. typhi*, and in the subsequent six months almost every specimen of urine and fæces has yielded *S. typhi*.

Case 3.—A mental defective female, aged 46, received chloramphenicol from the twenty-second day of her illness, when the typhoid fever appeared to be resolving naturally. Altogether she was given 20 g. in eight days. Her excreta remained negative for *S. typhi* until eighteen days after the chloramphenicol was stopped, when both urine and fæces yielded *S. typhi* v1 for two days. Daily specimens were negative for the next three weeks, but thereafter weekly examinations showed that she was excreting *S. typhi* in both urine and stools. She has now been under observation for eleven months and is still a chronic typhoid carrier.

DISCUSSION

In case 1 the patient received 31 g. of chloramphenicol in sixteen days for the original attack and 24·75 g. in thirteen days for the relapse, which responded even more dramatically than the original illness. She had been given 0·25 ml. and 0·5 ml. of T.A.B.C. twenty-one and seven days before her first illness, but neither this nor the combination of chloramphenicol, penicillin, and sulphatriad prevented her relapse. At no time did the urine yield *S. typhi*. Throughout both illnesses vitamin-B complex was given in the form of yeast tablets.

Cases 2 and 3 have become chronic typhoid carriers. In case 3 the chloramphenicol was begun late, when the disease was resolving naturally, and it might be argued that the development of the carrier state was largely a result of this delay and the small dosage given. However, in case 2 the chloramphenicol was started on the fourth day of illness and the patient received 32·5 g. in fourteen days, whereas the total dosage advocated at the Royal Society of Medicine discussion, already referred to, was 30 g. in fourteen days. So early and apparently adequate treatment with chloramphenicol, even when combined with penicillin and sulphatriad, does not invariably prevent the carrier state.

Throughout her early convalescence case 2 excreted *S. typhi* intermittently in both urine and fæces. It was thought that she had relapsed when she had a rigor on the sixty-third day from the start of her original illness and she was therefore given a further 25·5 g. of chloramphenicol, making 58 g. altogether. In fact, this was not a relapse, but why she developed jaundice on the day after her rigor is not easily explained. She had been in this hospital for the past five years and had no previous history of jaundice. Because of its comparatively short duration the jaundice is unlikely to have been due to hepatitis. The most probable diagnosis seems to be a small gall-stone with cholecystitis, and serological examinations showed that the jaundice was of an obstructive type.

The mechanism of the production of the carrier state in typhoid fever is still not fully understood, but the reason for the failure of chloramphenicol to prevent it may be that this condition may arise even in the prodromal period of the disease. Only 4 cases of typhoid fever have been treated with chloramphenicol at this hospital, and it is remarkable that 2 of them have become carriers. Nevertheless, Smadel,[1] in his large experience, has found no reason to believe that patients treated with chloramphenicol are more likely than others to develop the carrier state.

SUMMARY

Three adult mental-hospital patients with typhoid fever were treated with chloramphenicol. One relapsed and 2 have become chronic carriers, including a patient treated early with what is considered to be adequate dosage.

I wish to thank Dr. J. S. McGregor, the medical superintendent, for his help and permission to publish; Mr. D. C. Hubbard, senior laboratory technician; and the nurses who attended the patients.

Preliminary Communication

AMNIOTIC GRAFTS IN CHRONIC SKIN ULCERATION

Chronic ulcers on the legs in elderly people are notoriously difficult to treat. In 1939 I began to dress such ulcers with boiled human amnion, and I have found this treatment remarkably successful.

My original series up to 1942 consisted of seven bedridden patients aged 60–80, who had had ulcers for 4–15 years. All the patients had been in hospital for 3 years, and none of their ulcers showed any sign of healing. Amnion grafts were applied in six of these cases, the seventh being dressed with soft-paraffin gauze only, as a control. In 10 weeks the six ulcers treated with amnion had completely healed, whereas the control had not. The control ulcer was then treated with amnion and it healed in 5 weeks. A follow-up of these cases showed that none of the ulcers subsequently broke down, but six of the patients have since died of other causes. The seventh I examined this year; no further ulceration has occurred, and the skin over the old ulcer is thick and healthy.

My belief that amniotic membrane possesses some specific healing power was supported by the work of Chao et al.,[2] who used amnion to close dural defects. Penfield [3] later reported that if the amnion had not been boiled it led to the formation of fibrous adhesions. The same tendency was noted when amnion was used in the repair of tendons.[4] This stimulation of fibrous-tissue growth, combined with my own observations on epithelial repair, convinced me that amnion was an ideal covering for chronic skin ulcers. In 1949 therefore I started a new series of cases at Charing Cross Hospital, and so far there has not been a single failure.

PREPARATION OF AMNION

The "caul" is obtained from the obstetric wards within 24 hours of a delivery. It is cleaned and the amnion is carefully freed from chorion and clots. To be suitable for use the amnion must be thin, clear, tensile, and strong, with no yellow tinge from meconium staining.

The amnion is boiled for 7 minutes in normal saline and preferably used immediately. It can safely be kept dry in a sterile pot for 24 hours, but if not used in this time it should be discarded.

---

[2] Chao, Y., Humphreys, S., Penfield, W. *Brit. med. J.* 1940, i, 517.
[3] Penfield, W. *Ibid*, p. 668.
[4] Pinkerton, M. C. *Lancet*, 1942, i, 70.

An average confinement provides a piece of amnion about 8 inches square, which contracts on boiling to about 4 inches square.

TECHNIQUE

The patient is admitted to hospital, and the ulcer is scraped with a Volkmann's spoon under general anæsthesia. A dressing of 'Phenoxetol' cream is applied, covered with gauze, and left in situ for 5 days, after which the dressing is removed, the ulcer is gently cleaned, and the prepared sheet of amnion is spread carefully over it. I have found it best to apply the smooth side, which secretes the amniotic fluid in utero, to the ulcer. The area is next covered with soft-paraffin gauze and wool held in place by a pressure bandage. The patient is sent home to rest in bed, and no further treatment is required. The dressing is removed after 6–10 weeks, according to the size of the ulcer.

CASE-RECORDS

Case 1.—A man, aged 66, had had intermittent claudication with varicose ulceration of the left leg since 1948, and had already had an above-knee amputation of the right leg for the same condition. He had been in hospital from Nov. 13 to Dec. 15, 1948, during which time the ulcer only partially healed and then relapsed.

When seen in October, 1949, he had a large painful ulcer measuring 5×4 in. on the anterior surface of his left leg, with surrounding discoloration. He was treated with 'Priscol' (2-benzyl imidazolin hydrochloride, a peripheral vasodilator) and nicotinic acid, and a lumbar sympathectomy was performed by Mr. Norman Lake. A month later no further healing had taken place, and Mr. Lake asked me to try amnion grafting. On Jan. 3 this was done, but the ulcer was so extensive that only part of it could be covered with the material available, and a raw area the size of half a crown which remained was dressed with soft-paraffin gauze. The patient was sent home to bed for 10 weeks. When we inspected the ulcer at the end of this period it had completely healed except for the "half crown" area. Over the healed part of the ulcer the skin was healthy, elastic, and pink, not just a thin membrane overlying chronically infected granulation tissue. An amnion graft has since been applied to the remaining area, and we are awaiting results.

Case 2.—A man, aged 52, had had a varicose ulcer of the left leg and intermittent claudication for 6 years. The ulcer never healed and was a source of pain and discomfort. Thiersch and pinch grafts had been tried, and finally a pedicle graft, but all had broken down, apart from a small marginal area. A lumbar sympathectomy was performed in October, 1949. Three weeks later, on Nov. 17, I was asked to try amnion grafting. The patient was so distressed by his ulcer that he had actually agreed to have his leg amputated. On Dec. 8 I put on an amnion graft and sent him home to bed for 10 weeks. After this time the ulcer had completely healed. One might be tempted to say that it was the sympathectomy that resulted in the cure; perhaps it was, but similar ulcers have been healed without sympathectomy.

Case 3.—A diabetic man, aged 65, had a varicose ulcer on the inner side of his left ankle and gangrene of the left big toe. His varicose veins had previously been injected. The ulcer had been present for 10 years and had never healed. On Jan. 27, 1950, the ulcer was amnion grafted, and on March 16 it had completely healed.

Case 4.—A man, aged 48, had large ulcers on both legs. The one on the right leg measured 4 × 5 in. and extended from front to back on both sides. The left leg had a smaller ulcer over the medial malleolus. Owing to the patient's general condition and vascular calcification lumbar sympathectomy was considered inadvisable. On Nov. 17, 1949, I treated these ulcers with amnion, and on Feb. 22, 1950, they had completely healed, again with strong thick skin of extraordinarily good quality. The patient has been seen recently, and there is no sign of the areas breaking down.

Case 5.—A man, aged 50, had a chronic ulcer of his right leg dating from Nov. 21, 1949, when he had had a minor trauma to the scar of an old gunshot wound. The ulcer had not healed in spite of complete rest in bed for 4 weeks and penicillin therapy. On March 2, 1950, I applied an amnion graft to the area, and the patient was treated as an outpatient, since he refused to go to bed. A fortnight later the ulcer had healed with healthy skin.

Case 6.—A married woman, aged 48, had a varicose ulcer which remained unhealed after 16 weeks' rest in bed in hospital. It had healed completely and soundly 10 weeks after amnion grafting.

COMMENTS

All these patients say that, two or three days after the amnion is applied, the pain disappears from the ulcer, which is not so when other dressings are used. In principle this treatment follows the lines laid down by Winnett Orr and Trueta; and keeping the wound closed with an ideal membrane, such as amnion, seems to be particularly successful in the treatment of chronic ulceration. When varicose ulcers are encased in plaster-of-paris they heal slowly, and the granulations are thick and raised above the skin level, whereas with amnion grafting the granulation tissue is never raised above the skin margin, and healing takes place equally from all sides. When the soft-paraffin gauze dressing is removed, after 10 weeks, the ulcer is healed and there is no sign of the amnion over the actual ulcer site, but all round the edge of the ulcer the amnion is still fixed to the gauze. An interesting problem, which will require biopsy-study, is: What has become of the amnion covering the ulcer?

The properties of amnion are being investigated: a series of cases is being collected in which the results are recorded photographically; control trials are being carried out with other media, such as aluminium foil: and the amnion treatment is being tried in outpatients without rest in bed, and with and without preliminary scraping of the ulcers. Up to now we have found that ulcers heal with thicker skin if they are scraped before grafting. A few patients have complained of the smell from their ulcers, due to the products of saprophytic organisms, and there is the possibility that an accumulation of pus or gas-bubbles under the amniotic covering might prevent it adhering to the ulcer. I am therefore proposing to dust the ulcer lightly with penicillin-sulphathiazole powder before grafting.

The patients with chronic ulcers now attending outpatient departments could receive amniotic grafting and be sent home for 10 weeks rest in bed, after which they could be seen occasionally and ordered necessary preventive measures, such as elastic stockings, thick socks to prevent trauma, &c., by their own doctors. This should result in an appreciable reduction in outpatient attendances and a substantial saving in time for both patients and doctors. Moreover, if even the most minute varicose ulcer was treated by grafting as soon as it was seen by a doctor the period of rest in bed could probably be reduced to 2–3 weeks.

I should like to thank Mr. N. C. Lake, Mr. C. MacLeod, Mr. R. A. Fitzsimons, Mr. D. Trevor, and Dr. N. S. Plummer for kindly allowing me to treat their cases, and for the interest they have shown in this technique.

E. TROENSEGAARD-HANSEN
F.R.C.S.
Surgical Registrar.

Charing Cross Hospital,
London.

"... The Universities, with their museums and botanic gardens, are happy to forget what, in 1859, they were unable to resist. They contain no memorial of his work, and all the means of developing his doctrine they frustrate by an arrangement of teaching which the theory of evolution is not allowed to disturb. The old pedantic learning of botany and zoology, which Darwin treated as one subject, they continue to cleave asunder burying the halves under their ancient schedules of instruction."—C. D. DARLINGTON, D.SC., F.R.S., in a foreword to a reprint of the 1st edition of *On the Origin of Species*, by Charles Darwin. (*London: C. A. Watts. 15s.*)

Medical Societies

MEDICAL SOCIETY FOR THE CARE OF THE ELDERLY

The society's spring meeting was held in Leeds on April 21 and 22. The afternoon meeting on April 21 was held under the chairmanship of Prof. R. E. Tunbridge.

Cardiac Conditions.—Dr. Curtis Bain (Harrogate) remarked that in patients over the age of 70 the same conditions (including congenital and rheumatic disease) were encountered as in younger patients, and the methods of treatment were not affected by age. Sociological factors were very important in reablement. He emphasised the need to keep these patients in bed for as short a time as possible, and suggested that three weeks in bed was quite long enough for the average case of coronary thrombosis.

Senile Purpura.—Dr. R. N. Tattersall (Leeds) re-established this as a clinical entity. The condition was produced by trauma on altered skin and had a selective distribution on the face and extensor surface of the forearms. There was no evidence of dietary deficiency or of blood disorder, and the basic pathological lesion was an alteration in the skin collagen which became more pronounced with increasing years and was localised to the face and extensor surface of the forearms.

Cup Arthroplasty.—Mr. R. Broomhead (Leeds) demonstrated by means of films the technique and results of operative treatment with cup arthroplasty for osteoarthritis of the hip. His oldest patient was 68 years of age, but he mentioned cases in the U.S.A. operated on in the late 70s. It was important to operate as early in the course of the disease as possible and before muscular wasting and fibrosis were far advanced. Patients must be physically fit to undertake the strenuous course of physiotherapy required after operation.

Rheumatic Pain.—Dr. Trevor H. Howell described some new methods used by him in the treatment of rheumatic pain in the elderly. He reported good results from the pericapsular injection of tetraethylammonium bromide.

MEDICOSOCIAL PROBLEMS

On April 22, at the morning session, under the chairmanship of Mr. Peter McEwan (Bradford), the organisation of a geriatic service was discussed.

Mr. Roger Wilson (Hull) opened with a review of the social background. He emphasised that the increasing interest in the elderly did not merely indicate a change of mind: it was forced on us by the pressure of population changes. In 1947 one in six and a half of all adults were over the age of 65, and by 1977 the ratio would be one in four. Finance alone offered no solution, but finance could not be neglected. Every shilling added to the old-age pension cost the taxpayer £15 million per year, and by 1978 the cost of pensions at the present rates of benefit would be £512 million a year. Fortunately people did not necessarily retire on reaching the pensionable age; two-thirds of men continued in employment, and half the women who were working continued to do so. More than half the women over 60 continued to bear heavy domestic responsibilities, and by looking after grandchildren they often enabled younger women to remain in employment. Mr. Wilson emphasised the importance of the increasing average age of adults in accentuating conservative trends in public life, and thought that there was a real danger of old-age pensioners becoming a political pressure-group. There was also the danger in our highly organised society that only those who had retired would be able to give part-time service to public bodies, thus raising the average age of those administering such organisations.

Dr. Murray Melvin (Leeds) described the increasing demands which the ageing population made on the general practitioner. Apart from the increase in medical work, the G.P. was now expected by the relatives to carry out the functions performed in the past by the relieving officer. Dr. Melvin held that these duties could be performed by a liaison officer from the hospital, who should visit the patient at home and assess the social needs and the urgency of admission. Since old people had such low priority in the home-help scheme, the possibility of paying relatives who undertook their care might be considered. Some sort of physiotherapy should be available in the home, even if this was administered by those not fully qualified. Mobility was the essential in therapy. Every effort should be made to shorten the interval between the last time of going to bed and death.

Dr. E. D. Irvine (Dewsbury) described the function of the public-health department in organising liaison between the patient, the hospital, and the various ancillary services. He postulated that the prevention of a geriatric problem began in the school and with the various health services available to adults, which, if fully utilised, should lead to a healthy old age. The possibility that atmospheric pollution might be important in the causation of respiratory disease in old people should be investigated. It would also be valuable to investigate a group of happy and healthy old people to see if they had any factor in common.

Dr. Marjory Warren spoke on geriatrics as a specialty. She regarded the title as a challenge, and justified the existence of the specialty by quoting figures from her own and other units. She and her staff now managed in 180 beds the same number of patients that had previously occupied 520; and she did not think that the present number of hospital beds was inadequate if they were efficiently utilised. There was, however, a deficiency in social-amenity beds. She mentioned 50 hand-fed, bedridden, and incontinent patients transferred from elsewhere, all of whom had been in this state for at least two years. At the end of three months 20% had returned to their homes ambulant and independent, and a further 30% were up and dressed and were partially independent.

Dr. S. G. Laverty (Bradford) described his experiences as a hospital doctor performing domiciliary visits to patients on his waiting-list. He suggested that a doctor, rather than a lay officer, was the proper person to take over the relieving officer's duties. He sometimes found that it was the relatives, and not the old person, who needed hospital treatment. Home visits to old people living with their families, when it was possible to see three or even four generations at once, provided valuable material for study of the effects of heredity and environment.

LIVERPOOL MEDICAL INSTITUTION

At a meeting on March 23, with Mr. H. V. Forster, the vice-president, in the chair, Mr. Leslie J. Temple discussed the Undetected Foreign Body in the Bronchus. The cases he described included those of: (1) a seaman with part of a spectacle lens in his bronchus who was treated for a long time as a case of tuberculosis in a sanatorium; (2) a girl with a screw in the bronchus, apparently since childhood, who attended because of hæmoptysis; (3) a woman with a glass tube in the lung, no cause being found for its presence; and (4) a child with bronchiectasis due to rough grass inhaled through a pea-shooter.

Reviews of Books

Antibiotics

ROBERTSON PRATT, PH.D., associate professor of pharmacognosy and plant physiology, University of California College of Pharmacy; JEAN DUFRENOY, D.SCI., research associate in antibiotics, at the college. Philadelphia and London: J. B. Lippincott. 1949. Pp. 255. 40*s.*

THIS book has been written by a professor of pharmacognosy and by another non medical author, apparently mainly a bacteriologist. It attempts to describe the broad principles of antibiotics and antibiotic chemotherapy sufficiently comprehensively to satisfy those concerned with the health sciences, but not so technically as to discourage those whose major activities lie in other fields. Throughout, the bias is towards chemistry and bacteriology and the clinical paragraphs are secondary in importance and scope. It provides little technical information of direct use to the clinician or bacteriologist, but gives a broad account of antibiotics in relation to general biology and of the numerous chemical and bacteriological problems arising in these studies. A serviceable chapter explains the methods of industrial manufacture of these substances in simple language, and there are also chapters on each of the more important antibiotics including up-to-date accounts of 'Chloromycetin' and 'Aureomycin.' The chapter on the mechanisms of antibiotic action is less lucid than the others; this is due less to the fault of the authors than to the incompleteness of our present knowledge: what is only partially known cannot easily be explained. The paper, print, and format are pleasing, although the motto headings over each chapter seem irrelevant and fanciful. The book can be recommended to the general reader who is interested in this subject. It will not assist him directly in his clinical or bacteriological work but it will greatly broaden his conception of the whole subject.

Malignant Disease

JAMES F. PHILIP, CH.M. Aberd., F.R.C.S.E., radium officer, Aberdeen Royal Infirmary. Aberdeen: University Press. 1949. Pp. 238. 15*s.*

THIS survey describes the principles on which a cancer clinic should be founded and includes an analysis of the results of treatment for malignant disease at the Aberdeen Royal Infirmary from 1930 to 1939 inclusive. The records of any complete series of cancer cases such as this are valuable, and the book is sure of a welcome. Each of the important sites is dealt with in a separate section, the method of staging is given, and charts show the proportion in each stage and the method of treatment adopted. The table in which the results of treatment are set out is very simple, and when percentages are used they are crude rates with no allowance for intercurrent disease. In each section the methods employed in other centres are described and the results of the various methods compared, so that much useful information is made available both to surgeon and to radiotherapist. For instance it is found that of 411 cases of cancer of the stomach only 50 were considered to be operable; 20 patients of these 50 died in the postoperative period and only 7 survived five years. Cancer of the colon is the subject of detailed analysis by site; 286 cancers were found, of which 66 were operable, and 22 patients survived five years. For cancer of the rectum it is suggested that, while surgery is the treatment of choice, radium is still a useful palliative. Radiotherapy shows satisfactory results.

An appendix gives the survival-rates for histologically proven cases treated by radiotherapy in 1930–36, and compares them with rates for cases treated in 1940–43. In cancer of the skin the survival-rate rose from 42 to 57%, in cancer of the lip from 56 to 67%, in cancer of the tongue from 8 to 41%, in cancer of the mouth from 18 to 24%, and in cancer of the cervix from 29 to 36%. This is an example of the great improvement obtained when all the radiotherapy of a centre is guided into the hands of one experienced radiotherapist.

Evaluation of Chemotherapeutic Agents

Editor: COLIN M. MACLEOD, M.D. Symposium held at the New York Academy of Medicine, Section on Microbiology, March 25 and 26, 1948. New York: Columbia University Press. London: Oxford University Press. 28*s.*

THIS record of a symposium contains many pieces of valuable information which are not widely shared. The book is well printed, with a useful list of references on each chapter and suitable diagrams illustrating recent work. It is refreshing to find the word chemotherapy used in its original and comprehensive sense rather than as meaning little more than the use of the sulphonamides. The symposium emphasises the value of continuing to determine the concentrations of drugs in plasma and in blood, offers a well-timed warning about reasoning by analogy from one drug to another or from one infection to another, and recalls John Hunter's famous maxim "... but why think? Why not try the experiment?" Penicillin receives its proper share of attention and the influence of severe nutritional and other metabolic disturbances on effective chemotherapy is rightly stressed. The control and cure of rickettsial diseases has begun with the use of *p*-aminobenzoic acid and more recently with chloramphenicol and 'Aureomycin.' A suitable warning is given against expecting too much from the current revived interest in the chemotherapy of cancer. In all, a well-documented and instructive account of progress in the chemotherapeutic field.

Thérapeutique médicale oto-rhino-laryngologique

GEORGES PORTMANN, professeur de clinique oto-rhino-laryngologique à l'Université de Bordeaux. Paris: Doin. 1950. Pp. 315. Fr. 960.

HERE is a topical, brief, and elegant summary of the methods of non-surgical treatment which can be used in diseases of the ear, nose, and throat. More than half of the book consists of lists of prescriptions of medicaments, drops, and lotions to be used in diseases of the ear, nose, and throat. A regional classification of these diseases inevitably leads to some overlapping. The most serious defects are the absence of any discussion on the principles underlying the use of a particular drug, or of the results to be expected from its exhibition. A great variety of preparations is thus recommended without any critical evaluation, guidance, or instruction. About a quarter of the book deals with general medical methods of treatment, having good chapters on sulphonamides and penicillin, and even including a brief mention of streptomycin and tyrothricin. There is also a brief but very good account of modern electrical hearing-aids. In the rest of the book the various special methods of treatment necessary in this specialty are described and well illustrated: everything seems to have been included, from the technique of syringeing an ear to the Proetz method of performing suction-displacement. There is even a short chapter on aerosols.

The Diabetic Life (14th ed. London: J. & A. Churchill. Pp. 238. 10*s.* 6*d.*).—A fourteenth edition with 25 years of service behind it needs no puff. Dr. R. D. Lawrence remarks in his preface that the new health service, which has made insulin and other necessities free to diabetics, should now help to establish regional clinics, so that these patients can be given expert supervision in their own districts. He urges every patient to join the Diabetic Association, which safeguards the interests of its members, and, by providing funds for research, maintains the prospect of better treatment, and even of the prevention and cure, of diabetes.

English Index to Soviet Medical Publications Available in London Libraries, Vol. I, 1945-47 (London: H. K. Lewis. 1950. Pp. 93. 20*s.*).—Seventeen Russian periodicals are listed here. Those which have been fully covered by the *Quarterly Cumulative Index Medicus* have been purposely omitted. It is intended to publish later this year a second volume to cover 1948–49 and to include further journals of 1945–49, and thereafter to issue a further volume each year. No subject cross-references are given: these should be picked up in the *Index Medicus*, which has been used as a pattern for the arrangement of the text. The book has been edited on behalf of the Medical Committee of the Society for Cultural Relations with the U.S.S.R. by Mr. Donovan T. Richnell, deputy librarian, University of London.

THE LANCET

LONDON: SATURDAY, MAY 6, 1950

Cardiac Catheterisation

CATHETERISATION of the heart comes of age this year, and it now has an established place among the diagnostic procedures of all up-to-date cardiological centres. Following some tentative venous catheterisations by BLEICHROEDER[1] many years before, FORSSMANN,[2] in 1929, introduced a catheter into his own heart; but the time and circumstances were not propitious for further development of his bold technique. JIMÉNEZ DIAZ[3] obtained data by catheterisation for a single estimation of cardiac output in 1930, and then for a time catheterisation was used in Portugal and France for the injection of sodium iodide to outline the vessels at the root of the lung. But it was the work of COURNAND and his colleagues[4] in the U.S.A., who left a cardiac catheter in situ for long periods for measuring pressures and taking blood-samples, primarily for the study of pulmonary blood-flow, that established the safety of the procedure and led to its increasing use all over the world. Many thousands of cardiac catheterisations have since been performed, and the number of accidents reported is extremely small.

Since BLALOCK and TAUSSIG[5] showed that some forms of congenital cyanotic heart-disease could be treated surgically, there has been a demand for more exact diagnosis in these cases, and, as a result, cardiac catheterisation has become widely accepted as a preliminary to cardiac surgery, though the risks involved are slightly greater in these cyanotic cases. The blue child with a congenital heart lesion and thick viscid blood may be peculiarly liable to thrombotic accidents, and one case of extensive thrombosis of the inferior vena cava after cardiac catheterisation has been reported from Montreal.[6] Transient hemiplegia has also followed the procedure.[7] If tiny thrombi form on the tip of the catheter and escape into the circulation they may do little harm in a normal anatomical circulation, for they are trapped in the lung capillaries. In the patient with a right-to-left shunt, however, such small emboli may block cerebral or other important arteries. At first it was unusual to pass the catheter beyond the right atrium, and no harm has ever been reported from catheterisation in this position. But the catheter is now often passed into the right ventricle and through it into the pulmonary artery. Extrasystoles are readily precipitated by irritation of the right ventricle, especially in the region of the outflow tract,[8] but these may be avoided by readjusting the position of the catheter or by injecting 5–10 ml. of 2% procaine. In ischæmic heart-disease, where sudden death from ventricular paroxysmal tachycardia or fibrillation is a known risk, the catheter may possibly precipitate disaster. When catheterisation is undertaken in such subjects full electrocardiographic control is necessary at all stages, and judicious retreat is advisable if premature beats are not readily controlled. There has been a notable absence of published necropsy reports on patients who had been catheterised shortly before death, but BANFIELD and his colleagues[9] have collected details of 30 unpublished cases, and in none of these were any lesions ascribable to the catheterisation demonstrated. In dogs, however, minute lesions have been found where the catheter impinged on the endocardium,[10] and, though the less active human heart is probably less liable to injury, it would be reassuring if the extent of the risk could be assessed by pooling the data from many clinics. The present impression is that catheterisation is safer than, for example, gastroscopy or even lumbar puncture.

In the early days of cardiac catheterisation, pressure measurements inside the heart were made by the simplest means. COURNAND and his colleagues[11] were the first to record intracardiac pressures optically and to demonstrate the value of these records. Sensitive membrane manometers of various types attached to the outer end of the catheter will record the pressure in the right ventricle accurately during diastole and fairly accurately during systole. But the long catheter has a damping effect on the recording system, and many of the published pressure curves obviously contain artefacts. The Mayo Clinic workers[12] have obtained more satisfactory pressure curves by embodying a pressure-recording device in the tip of the catheter. Discussing the value of catheterisation in the diagnosis of congenital disorders, and the difficulties that may arise in interpreting the findings, they conclude that the investigation of an obscure congenital heart case is at present bound to be a protracted and complex procedure requiring a skilled team. It had been hoped at one time that the need for tedious analyses of the oxygen content of blood-samples from various parts of the heart might be eliminated by using some system of electrical recording of the oximeter type. But such methods have not proved accurate enough, except to give an approximate indication of the oxygen content which will be checked later by more direct methods.[13] In theory, by taking single samples of blood from the right heart it should be possible to calculate the relative volume of blood shunted through

but important sections of the population were receiving amounts of calcium, vitamin A, and riboflavine well below any acceptable physiological standard. These findings confirm the impression of the casual visitor to Dublin. There he will find hotels and restaurants in which those with money may buy unlimited quantities of the best and richest foods. But outside he will find beggars in the streets who look undernourished. How big are the underfed and overfed minorities in Dublin and other Irish cities is uncertain; probably both are small. For the majority the hard facts of pounds, shillings, and pence ensure a diet that is frugal but sufficient, and in most respects differs little in nutritional value from the diets in England today. Tradition, however, still determines that all Irish families, whatever their economic status and both in town and country, eat more potatoes and less bread than corresponding families in England. The Irish also eat little cheese or fruit and are largely dependent on the potato for supplies of vitamin C.

The four parts of the Nutrition Survey so far published cover only the findings of the dietary surveys. While these were in progress a widespread clinical nutritional survey was also undertaken. This is now completed, but the data are not yet fully analysed, and until these clinical findings are published the significance of the dietary surveys cannot be finally appraised. Meanwhile we can congratulate the Irish on planning and carrying out a large-scale nutritional survey on a sound statistical basis. Probably no other country now possesses such accurate knowledge of what its people eat. When the final reports are written up it is to be hoped that those responsible for this excellent work will discard the cloak of anonymity which enshrouds the first four parts.

The Biology of Antibiotics

NOWADAYS, when penicillin has ceased to be a wonder and streptomycin is beginning to be "last year's model," when even chloramphenicol and 'Aureomycin' are losing their novelty though they are not yet released for everyday use, and when valuable new antibiotics are reported every month or two, one is apt to regard the moulds and similar organisms as convenient and highly efficient pharmaceutical laboratories provided by a beneficent providence to produce remedies for man's worldly ills. And if we discard this anthropocentric view as too naïve, the question arises why *do* living organisms manufacture this vast variety of complex compounds apparently directed against a fairly limited range of bacteria and other micro-organisms? Analysing the matter further, it may be asked why Penicillia should be so determined to eradicate gram-positive bacteria, whereas the Streptomycetes seem to be a particularly vicious class ready to pounce on both gram-positive and gram-negative micro-organisms, not to mention various rickettsias and viruses. Within the narrow limits of medicine these characteristics seem inexplicable; but when they are seen against the background of general biology, as PRATT and DUFRENOY show in their book reviewed on p. 862, some of these explanations begin to appear.

The component members of any society, whether they are human beings or any other living organisms, continuously influence, and are influenced by, their environment. Further, the neighbouring beings or organisms or cells constitute an important part of that environment. These principles are as true for the growth of bacteria as for the waxing and waning of civilisations. The relations between different organisms living in the same space may be of various kinds. Their influences on each other may be mutually beneficial, when the position is called symbiosis. One organism may use the other to supply it with food and protection against the outside world, as is done by well-adapted parasites. Finally, one organism may inhibit or altogether prevent the growth of another, presumably to gain more *Lebensraum* and food by eliminating its competitors; this is the relationship which VUILLEMIN, in 1889, called "antibiosis," from which the modern term "antibiotic" is derived, though its sense is now narrowed to only part of this field. Such antibiosis is not restricted to bacteria. Many higher plants possess means of keeping bacteria in check, and our own enzyme lysozyme is a similar protective mechanism against bacteria. Some plants exert an antibiotic action against other plants. Thus in the sparsely vegetated Colorado deserts there is a kind of daisy (encelia) which prevents the growth of other plants in the neighbourhood by excreting a toxic substance (3-acetyl-6-methoxybenzaldehyde) which diffuses out from the centre.

The apparently obliging behaviour of the moulds, which labour to cure man's ills, is an artefact produced by anthropocentrism and selection. Man pays particular attention to the factors in his environment that do him harm or good. (Especially, a cynic would say, to those that do him harm.) Thus medical textbooks describe bacteriology in terms of the pathogenic micro-organisms and hardly mention the much more numerous non-pathogenic ones. In reality most bacteria ignore man even more than he ignores them, and the few micro-organisms that produce useful therapeutic agents are a tiny minority among the millions that do not. Their apparently kind action is merely one of a great variety of characters, which has been brought into prominence by man's careful selection of something which will be useful to him. The fineness of discrimination needed in this selection may be judged from WAKSMAN's statement that about 10,000 cultures of organisms were studied in his laboratory alone in the search for useful antibiotics: about 1000 were found to have antibacterial properties; when these were grown in liquid media only about 100 produced specific antibacterial substances; of these, 10 substances have been isolated and described; but only 1 has proved to be of therapeutic importance—namely, streptomycin. To be of therapeutic value, an antibiotic substance must be highly poisonous to some pathogenic bacteria but non-poisonous to the patient. Presumably such a substance is poisonous to an organism because it blocks some essential metabolic pathway. If it blocks a pathway common to all living cells, then it has a wide range of action but it is toxic to the host and so useless. If it blocks a pathway which is irreplaceable only in a small group of bacteria, then the substance has a highly specific action, but it is of therapeutic value only if this small group of bacteria happens to contain important pathogens. All gradations between these extremes of antibiotic action various abnormal orifices. In practice, however, as ROSSIER[14] and other speakers at last year's Swiss Cardiological Congress pointed out, calculations on this basis may be misleading, because streams of blood of different composition entering one chamber of the heart are not necessarily completely and immediately mixed. Shunts can readily be recognised and confirmed on the evidence of single catheter samples, but estimations of their magnitude call for the greatest care and checking by multiple samples. The investigation of congenital heart-disease by catheterisation therefore involves the use of complex pressure-recording devices and critical analysis of the blood-samples obtained, and the unavoidably lengthy sessions, in which the positions of the catheter are followed on the X-ray screen, may expose both the patient and the investigating team to a dangerous dose of radiation unless a time limit is set on screening exposures and the observers are duly protected.[15] The possibilities of error in making cardiac-output estimations on single samples from the right heart were recognised early, and one set of measurements,[16] in subjects with more or less normal circulations, indicates that the coefficient of variation in the cardiac output obtained by the direct Fick method is ± 6 %. This means that estimations must differ by at least 12% to be statistically significant; and when the circulation is rapid, as in anæmia or emphysema, and arteriovenous oxygen differences may be small, the margin for error in cardiac-output calculations is probably still wider.

Hitherto catheterisation has been confined to the right side of the heart. To reach the left ventricle the catheter must be passed against the arterial blood-stream, and arterial spasm is likely to block its passage. Moreover, the aortic valve opens for only a fifth of a second, and it is probably not wide open even then, for ZIMMERMAN and his colleagues,[17] who tried passing a catheter up the ulnar artery, failed to get it through the valve in 5 normal people, though they were successful in 11 patients with aortic insufficiency. The risks of damaging the valves or blocking a coronary ostium, however, are likely to deter others from attempting this feat.

The present position then may be summed up as follows. Cardiac catheterisation of the right heart is remarkably safe and is fully justified in the preoperative investigation of congenital heart-disease. With the advent of surgery in many forms of acquired heart-disease, such as mitral stenosis, catheterisation may also yield results of vital and decisive importance for the future welfare of these patients. While the technical problems involved in extracting the maximum amount of information from a catheter session are still great, such investigations should be restricted to the centres with a considerable experience of the method. In these centres the technique is also justifiably used to advance our knowledge of grave circulatory disease, which can now claim to be the "Captain of the Men of Death." But, as MAHAIM says,[18] "The method must be applied with discernment, humanity, and with respect to the patient."

The Irishman's Food

HISTORY can provide no more striking example of the vagaries of fortune than the changing lot of the Irish peasant in the last hundred years. At the time of the great famine in 1845–47, the story of which has been brilliantly retold by SALAMAN in his *History and Social Influence of the Potato*, a large proportion of the poor people in Ireland were subsisting almost wholly on potatoes. Owing to an insufficiency of land and the uncertainties of agriculture, the Irish peasant's hold on life was then as precarious as it often is now in the rice-growing countries of the East. Hunger was his daily companion; starvation a not infrequent intruder. Further, the almost exclusive rôle of the potato in the economic life of the peasants enabled the economically stronger landlords to dominate them completely and reduce them to a state of serfdom paralleled by the absolute subservience of the potato-eating natives of the Andes to their Inca rulers. SALAMAN has demonstrated convincingly how the cultivation of the potato by an agricultural community to the exclusion of all other crops reduces that community to the lowest levels of human degradation. The vast difference in the conditions of today is revealed in the reports of the National Nutrition Survey,[1] sponsored by the Medical Research Council of Ireland, discussed at a meeting of the Nutrition Society in Dublin on April 15. The food consumption of 948 families of small farmers, in all parts of Ireland except Ulster, was determined by weighing over a period of a week. The average weekly consumption per person was 11·1 oz. of butter, 11·6 oz. of sugar, 9·2 pints of milk, 6·4 eggs, 10·6 oz. of bacon, 25·8 oz. of other meat, 162·7 oz. of potato, 65·5 oz. of flour, and 38·2 oz. of bread. These figures will satisfy the dictates of the most rigid nutritionists, and the diet they represent would make the ordinary British citizen's mouth water. Another survey of 200 families cultivating small holdings on poor land on the west coast showed that here the living was not so high, though physiological requirements were more than met. The main reason for this extraordinary change in a hundred years is the disappearance of the landlords. An Irish speaker at the Nutrition Society meeting said: "The Irish peasant is the only farmer in Europe today who owns his own land." This striking statement went unchallenged, and, as regards Ireland at least, represents the facts. More than to any other factor, the Irish peasant owes the change in his fortunes and his satisfactory diet to the present system of land tenure.

In the urban population the general position is not so uniformly satisfactory. The surveys of 500 Dublin families, 329 families in other large towns, and 516 families in small towns show that economic factors play a big part in determining the townsman's diet. Thus the average weekly consumption of milk per head varied at different income levels from 2·7 to 6·7 pints; of eggs from 1·0 to 5·9; of meat from 8·6 to 55·4 oz.; and of vegetables from 12·6 to 41·9 oz. Consumption of bread and potatoes was always adequate. Analyses revealed no serious shortage of calories or proteins in any large group, the local level also, it is hard to understand why this country fails to learn the lessons of the past, and persists in manufacturing ad-hoc authorities to undertake its services, instead of facing boldly the reform of local government."

CARDIAC MASSAGE SUCCEEDS AFTER 7 HOURS

Few doctors would now contend that when a patient's heart stops in the operating-theatre the best thing to do is to inject camphor or some other analeptic. More than a generation of medical students have been taught that the only hope lies in cardiac massage, which not only stimulates whatever power of contraction the heart still possesses but also supplies blood to the cardiac muscle and to the cerebral cortex. Not more than a few minutes may elapse between cardiac arrest and the start of cardiac massage if the manœuvre is to succeed, and that may be why so few permanent successes have been reported. Resuscitation by this means is always dramatic, and it is understandable that even a straightforward case has news value. The case lately reported in the *New York Times*,[1] however, has special claims to novelty. A man of 65 was having an abdominal operation when he collapsed and the anæsthetist said he was dead. The surgeon thereupon opened the chest and gave cardiac massage for 2½ hours. At the end of this the patient was believed to be "again living" and was about to be moved to his room. Then his heart stopped again. This time cardiac massage was maintained for nearly 4 hours, but the patient ultimately recovered and is now walking about the hospital. According to one story [2] he is even planning to take the surgeon with him on a fishing trip.

THE NEW HUMANITIES

"The humanities" are defined by the *Oxford English Dictionary* as "learning or literature concerned with human culture, as grammer, rhetoric, poetry and esp. the ancient Latin and Greek classics." In our changing times this definition seems unsatisfying. Asked where to look for learning or literature concerned with human culture, few men would nowadays turn to grammar or rhetoric, as we use the terms, and not very many to poetry; their hands would more readily stray to texts on anthropology, social history, or preventive medicine. To some extent it must be so; science has taught us to weigh and measure, and the duty of exactness lies heavy upon us—even tempting us at times to believe that what is imponderable cannot exist. But the old humanities, as they were taught to our fathers in medicine, did something more than entertain or bore them, according to their temperaments; just as advances in science did something more to our poets and classical scholars than startle or annoy them—as Prof. John Fulton, giving the Ludwig Mond lecture [3] at Manchester University last year, showed by many a well-chosen quotation. Each aspect of learning drew upon and was nourished by the other. He recalled Osler's words on the same subject:

> "One of the marvels, so commonplace that it has ceased to be marvellous, is the deep rooting of our civilisation in the soil of Greece and Rome—much of our dogmatic religion, practically all the philosophies, the models of our literature, the ideals of our democratic freedom, the fine and the technical arts, the fundamentals of science and the basis of our law. The Humanities bring the students into contact with the master minds who gave us these things—with the dead who never die, with those immortal lives 'not of now or of yesterday but which always were.'"

It was an experience modern students well may envy, peering out, as they hew their way through the thicket of a crowded curriculum, at the spacious rides and noble vistas which refreshed their forerunners. How can they be helped through the trees in time to take a look at the wood? There is not much hope that they will revert to the study of Latin and Greek, as Professor Fulton is well aware; but they may be taught to contemplate the past in a different way, and to contemplate it, he suggests, as George Sarton did, thirty years ago, "from the summit of modern science, with the whole of human experience at his disposal and with a heart full of hope." It can be done, he believes, if teachers will approach the sciences historically, placing them within the framework of general history. By thus drawing on our cultural heritage—the humanities—they can give perspective and meaning to the sciences. They have, moreover, the corresponding duty of seeing that no man graduates from a modern university without having some contact with the sciences, especially the methods of science: without that he cannot understand the world he lives in.

HOSPITAL RECORDS OF PSYCHIATRIC PATIENTS

Interest in "patient documentation" in hospitals continues to grow. In the *Bethlem Royal Hospital and the Maudsley Hospital Records Handbook*, prepared by Dr. C. P. Blacker, the application of the all-conquering unit system to a psychiatric teaching unit is described.

The usefulness of a records handbook in any large hospital is obvious: to the short-service junior member of the professional staff it is a light upon dark places, and to the records department it is a court of appeal. The Bethlem and Maudsley booklet is open to criticism as being less simple than the system it describes. The new doctor has to read through a good deal of detail about the mechanics of the records system before he learns that his share of the work basically consists in (*a*) contributing adequate and legible clinical notes, (*b*) supervising the notes of his juniors to the end that their notes also are adequate and legible, and (*c*) recording and coding diagnoses as soon as a case is closed. It is true that the more he knows about the mechanics of the system, the less likely is he to fall foul of it, but his introduction to the proformas, the decennially arranged master name-file, the registry index cards, the numbering system, the colour signals, and the punch-card should perhaps be less formidable. In other respects, however, Dr. Blacker and his records subcommittee have notably succeeded in what is a specially difficult task. They have homogenised the clinical records of two hospitals 9 miles apart, bringing together (ultimately) ward, clinic, and domiciliary notes. They have achieved the ideal of one patient, one hospital number. They have devised a method of dealing with that perennial nuisance, the outpatient record which cannot be closed because the patient has not been discharged but has simply given up coming to hospital. They have centralised the storage of closed case-records. They have prescribed the order in which the sheets comprising a closed record are to be arranged for filing. They have set up a system whereby interesting data are abstracted routinely from closed case-records and transferred to punch-cards for subsequent study. Their handbook tells everyone on the "line" how to do his duty—how to register a new patient, how to allot a number which will not be duplicated, how to close a record, how to make an abstract, and how to check records for omissions. Definitions are given, and also an extract from the new International Statistical Classification of Diseases and Causes of Death, listing mental, psychoneurotic, and personality disorders.

Any who are shirking the modernisation of archaic hospital record systems (plural numbering, separate ward and clinic notes, bound volumes, and the rest of the familiar hindrances) would do well to look through Dr. Blacker's handbook. It will not tell them how to reorganise the records of a general hospital, but it is

occur in nature, but it is only a special few in the middle of the range which have been selected by man for medical use.

Why the Penicillia should be particularly antagonistic to gram-negative cocci, while Streptomycetes inhibit gram-negative ones, is still obscure. Further research may reveal some reason for this antagonism in the natural history of the Penicillia. It may be just a case of overlapping, where a mechanism, devised by an organism for one purpose, happens to react beneficially in quite a different biological system elsewhere with which it could never have come into contact by natural means. Thus the cinchona alkaloids are used by man to destroy malaria parasites in his blood; yet the cinchona tree could never have come into biological contact with Plasmodia during its evolutionary history, and it must have developed these alkaloids for some purpose or under some stimulus of its own. Similarly morphine reacts on the human cerebral cortex so as to relieve pain, but this cannot be the reason for its synthesis by the opium poppy. We must conclude that now and again a biological key happens to fit a biological lock quite remote from the one for which it was primarily shaped. Whether this applies to the selective action of penicillin on staphylococci or of chloramphenicol on rickettsias can only be solved by further research on the antibiotics. Work began in this field seventy years ago with Pasteur and Joubert, but it is only in the past decade that it has been pursued with system, energy, and great resources. Progress, which was initially so slow, is now so fast that we may reasonably expect to see these and many other questions answered in the near future.

Annotations

BLOOD DONORS

The men and women whose blood is used for transfusions in increasing amounts year by year probably receive little thought except from those concerned with their recruitment and organisation, or when one of them has the rare misfortune to suffer temporary disablement and sues for compensation. That recourse to law should be necessary to secure compensation is regrettable. In proportion to the total number of donors who are bled each year, the number who have to complain of the way in which they have been treated is very small, and very few of these have to seek financial compensation for loss of wages or expenses incurred by their temporary disablement. In the case recently reported,[1] a donor's arm had become infected. This complication may be unpleasant, causing inconvenience and perhaps anxiety; but fortunately it is rare. In the years 1946–49 infection of the site of venepuncture was reported to the regional transfusion centres on some 44 occasions. During this period some 1,384,000 donors were bled by these centres, so the incidence of infection was about 1 in 31,450 donors bled. In 7 out of the 44 instances it seemed unlikely that the infection was attributable to the venepuncture itself; and, omitting these, the incidence of infection due to venepuncture was about 1 in 37,000. There were probably further cases which were not reported to the centres; but it may be inferred that very few, or none, of these were serious. Of the 44 donors who did report, only 6, or 1 in 230,666, asked for financial compensation; and in each case this was paid without recourse to law. In a smaller series of some 750,000 donors bled during the war years the incidence of infection of the site of venepuncture was about the same—namely, 1 in 31,500.

The medical services and patients of this country owe a considerable debt to their voluntary blood donors; and, though these are repaid mainly by the satisfaction of knowing that their gifts of blood have been used to relieve suffering, we cannot do less than ensure that the care they get is of a high order. The responsibilities to the donor of those who arrange the donor clinics and take the blood are great. The apparent simplicity of this commonplace manœuvre may tend after a while to obscure the need for an immaculate technique carried out by a skilled and practised operator. With constant repetition, venepuncture becomes a dull occupation; but it should not be undertaken in a lighthearted or careless manner, and it should remain a medical responsibility. Nor should it be forgotten that the voluntary blood donor deserves the best, medically and in other ways. This implies, among other things, a polite and friendly atmosphere, a reasonable standard of comfort, and a competent operator who will not have to "dig for victory" with each needle. Donors who have been badly treated in any way do not come back, nor are they likely to persuade their friends to become donors. Should these volunteers be unlucky enough to suffer injury or loss attributable to the donation of blood, requests for compensation should be considered sympathetically and rapidly.

OPINIONS FROM EASTBOURNE

The Chancellor of the Exchequer has suggested that the proportion of the national income that can be devoted to health services has now reached its upper limit. The Congress of the Royal Sanitary Institute, held in Eastbourne from April 24 to 28, revealed lively concern that available funds are not being used to the best advantage. Thus Earl de la Warr, in his inaugural address as president of the congress, spoke forcefully about the imbalance between expenditure on the curative and on the preventive services. "Last year," he said, "Exchequer and personal payments amounted to over £450 million for the National Health scheme, and during the same period the sum of £9 million was allowed for subsidising new permanent houses, and just over £6 million for the school health services. 'Clinics and hospitals are great and wonderful institutions . . . but if we had to choose between a hospital bed and having a house to ourselves, there is not much doubt where our choice would lie, on both personal and health grounds." Dr. H. C. Maurice Williams, president of the conference of medical officers of health, spoke in similar vein. "With a limit on national expenditure, a stage has been reached when the relative values between an extension of the social services and the rehousing of the people ought to be properly assessed. It appears illogical to have reduced for financial reasons the erection of permanent houses by 25% during the last two years, whilst the expenditure on other less essential social welfare is going ahead by leaps and bounds." Our preoccupation with curative services was also criticised by Prof. James Mackintosh, president of the preventive-medicine section. There had, he remarked, been no broad conception of a national *health* policy, either in the National Health Service Act or in the plans which had been put forward since the Act came into force. "On the contrary, there has been an unmistakable tendency to split the rounded concept of national health into artificial segments, each under a different government department. This creates a muddle of central authorities competing for the supervision of local health services at the very time when one might have hoped for greater coordination and economy of effort. . . . At

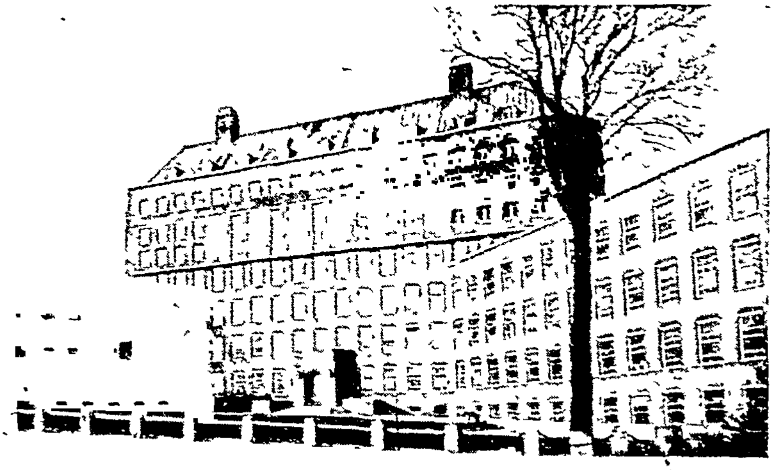
NATIONAL INSTITUTE FOR MEDICAL RESEARCH

Opening of New Building

TODAY, Friday, May 5, His Majesty the King opens the new building of the National Institute for Medical Research, at Mill Hill, London. Construction began as long ago as 1937 and the outer shell was finished in 1940, when work had to be discontinued. From 1942 until 1946 it was used by the Royal Navy as a training-centre for the W.R.N.S., and it was only last November that departments began to move from the old headquarters in Hampstead.

This is not the first time that war has delayed plans for the institute's development. In 1914 the Mount Vernon Hospital, Hampstead, was purchased by the Medical Research Committee (the precursor of the Medical Research Council), which had been set up a year before. This building was to be the Committee's main research establishment—as the present institute is the Medical Research Council's—but war intervened, and the building at Hampstead was first brought into use in 1920.



Exterior of the new building.

[*Associated Press*

In 1922 the council purchased an estate at Mill Hill, where farm laboratories and other buildings were erected. In 1936 a demand for further expansion of the institute arose from the need for extension of research in chemotherapy; and, since the possibilities at Hampstead were by then exhausted, it was decided that a new and larger building should be constructed on the Mill Hill site.

RETROSPECT

Though the building is new, the policy, as Sir Charles Harington, F.R.S., director of the institute, has made clear,[1] will remain the same. This policy has remained unchanged since it was first set out by the Medical Research Committee in their first report (1915):

> "The object of the research is the extension of medical knowledge with the view of increasing our powers of preserving health and preventing or combating disease. But otherwise than that this is to be the guiding aim, the actual field of research is not limited and is to be wide enough to include, so far as may from time to time be found desirable, all researches bearing on health or disease, whether or not such researches have any direct or immediate bearing on any particular disease or class of diseases, provided that they are judged to be useful in promoting the attainment of the above object."

The Committee decided on four methods by which to achieve these aims: (1) the employment of full-time investigators in centralised laboratories; (2) the appointment of full-time and part-time investigators in hospitals and elsewhere for special researches; (3) the provision of assistance grants to workers in academic institutions engaged in independent researches in the general field of interest; and (4) the maintenance of a statistical department. Under the National Insurance Act of 1911, one penny per insured person was provided from public funds for purposes of research; and in the first year this yielded £55,000. The sum allotted for current expenditure by the council in 1948–49 was £770,000.

The work of the council, and of the institute, has all along been conducted, in Sir Charles Harington's words "with almost academic freedom." Departmentalisation has been abjured: but teamwork has become increasingly prominent.

> "It seems to me," Sir Charles has said,[1] "that the history of the virus work at the Institute . . . forms a good illustration of effective team work in medical research, although at no time has there been any pretence at the formal constitution of a team. It is perfectly clear that the field of scientific effort covered by the research as a whole has been so wide that no one man unaided could have made much progress. On the other hand, at the outset of the investigation it was quite impossible to predict the devious paths which would have to be followed and the different branches of science into which excursions would have to be made. In these circumstances the course which was actually followed seems to have been the best, the essential feature being readiness at all times to extend the investigation in any desired direction by the addition of the help of an appropriate worker. In this way there is in fact ultimately formed a team of investigators whose efforts are all generally directed to the same end; but the team is never rigidly defined; it grows only in response to the demands of the work, and the individual members retain a considerable degree of scientific independence and scope

certainly good evidence that the unit principle can be applied successfully in circumstances far more complex than those existing in any ordinary general hospital.

HEALTH AND SAFETY IN MINES

COAL-MINING is one of the most hazardous occupations. The latest reports of the chief inspector[1] and the electrical inspector[2] of mines offer no cause for complacency with the safety or the control of disease. Nevertheless in recent years there has been a fairly steady decline both in fatal and in other serious accidents. Between 1928 and 1948 fatalities fell from 103 to 65 per 100.000 employed, and serious injuries from 437 to 390. (In 1948 factory workers, numbering some $6^1/_2$ million, suffered a fatality-rate of only 8 per 100,000 employed.)

The chief causes of accidents were "falls of ground" and "haulage"; 243 persons were killed and 905 seriously injured by falls, and 109 killed and 618 injured by haulage accidents. The chief inspector rightly points out that the combined accident figure is the only one that matters; it is pure chance whether a man is killed or seriously injured by a fall of ground. The increasing use of locomotives and trunk conveyors for underground transport is one of the chief factors in the decrease in haulage accidents; the practice adopted in the Dutch State mines of providing a driver's seat and controls at each end of the locomotive should be followed here. Serious accidents occurred through contact with the coal-conveyor, often due to riding or stepping on the conveyor belt—a forbidden practice. Fires on conveyor belts can cause serious loss of life, as was tragically demonstrated at Whitfield Colliery, North Staffs, where six men died as a result of one such accident.

In 1948 there were no major underground explosions, but there were seven minor fire-damp explosions causing severe injury; in four cases smoking was the immediate cause, and in every case the ventilation in that part of the mine was found to be defective. Accidents from electricity resulted in the death of 3 and serious injury of 66. Nearly all these accidents occurred underground, and often the use of unscreened trailing cables was the cause—the electrical inspector rightly condemns the continued use of such dangerous apparatus. At the same time, it is satisfactory that increased use of electrical horse-power in mines is not being reflected in an increased number of electrical accidents. Since 1938, accidents due to shot-firing have increased by 57%. There has been an increase in the amount of explosive used, and the chief cause of accidents has been failure to take proper cover at the moment of firing. Surface accidents are usually due to moving wagons or tubs, to slipping or stumbling, or to contact with moving machines.

Study of the chief inspector's report induces the depressing conclusion that far too many mining accidents are caused by negligence on the part of managements, or deliberate contravention of orders or personal carelessness on the part of men working in or about the pits. The most important preventive measure would appear to be instruction in the need for, and methods of, personal safety. Dangerous practices, such as smoking in forbidden areas, should be severely dealt with; and supervision—admittedly difficult in a mine—needs strengthening. The scope of training is, in fact, being widened; and in 1948 some 41,600 persons received preliminary instruction either at a colliery or in a training centre. The reorganisation and extension of the Mines Rescue Service and the provision of properly trained and equipped first-aid squads underground have gone far to ensure that skilled help is quickly forthcoming in the event of an accident. The establishment of pit-head surgeries is also proceeding, and 58 State-registered nurses are now employed in coal-mines, all working under medical supervision.

During the year, 4291 persons were certified as suffering from pneumoconiosis. Comparison with previous years is not easy, owing to the changed basis for notification under the National Insurance (Industrial Injuries, Prescribed Diseases) Regulations, which came into force on June 30, 1948. The employment of the pneumoconiotic miner who is able to work is one of the most serious problems confronting the country today. The industry cannot afford to lose all those who are certified as having the disease, and the provision in all collieries of sufficient working places with "approved dust conditions" demands urgent attention The chief inspector rightly declares that the prevention of pneumoconiosis depends on "effective measures being taken to limit or decrease the amount of airborne dust as a whole," and that these measures consist in devising coal-mining methods which produce the minimum of dust, and in effective methods for suppressing whatever dust is produced. Nystagmus is probably the next most important disease affecting miners. Its exact cause is still uncertain, but there is no doubt that insufficient illumination is a major contributory factor. The lighting in our coal-mines, particularly at the face, is nearly always insufficient; and, although improvements are now in train, it is doubtful whether these will be fully effective in preventing further cases.

Meanwhile, proper maintenance of existing lighting equipment, whitewashing headway surfaces, and the use of inert dusts with low absorption factors can make the most of incidental light. The chief inspector draws attention to the use in laboratories and in certain maintenance operations of such substances as benzene, carbon tetrachloride, and trichlorethylene, and he urges that attention be paid to the recommended maximum permissible concentrations and to training workers in the necessary precautions. One does not usually associate coal-mining with the use of toxic solvents, and this timely reminder provides a further example of the diversity of risks to health in an industry.

THE MEDICAL BILL

THE Medical Bill meets many of the recommendations of the British Medical Association and the two defence societies; but all these bodies, with varying emphasis, would like to see some further improvements. Thus they all favour some further increase in the number of elected members of the General Medical Council, and believe that at least a third of the disciplinary committee should be elected members. The Medical Defence Union thinks a disciplinary committee of 19 too large: it would prefer 12. All three bodies want it laid down that no member of the council who has made a preliminary examination of a case shall sit on the committee hearing that case. All again agree that (except in matters arising from court proceedings) complaints against practitioners shall not be considered unless made formally in writing—a proposal designed to prevent vague charges being made to the council by official bodies which are unwilling to substantiate them. Amendments are also suggested to prevent some future council from removing a convicted doctor from the Medical Register without holding an inquiry of their own. It is pointed out that nowadays a potential penalty of £20 is not enough to deter people from falsely representing themselves to the public as registered medical practitioners; and the M.D.U. also raises the interesting question whether a doctor should be at liberty to use a registrable qualification unless this is in fact registered by the G.M.C.

DR. R. G. GORDON, physician to the Royal United Hospital, Bath, died on April 26.

Automatic radioactive-isotope counter.

W.H.O.'s World Influenza Centre is administered from the institute, which is also responsible for many international biological standards.

THE BUILDING

The new institute, the largest of its kind in the Commonwealth, will ultimately suffice for about 100 scientific workers and 250–300 assistants. The building, designed by Mr. Maxwell Ayrton, F.R.I.B.A., is situated on the Ridgeway, Mill Hill, at the south-east corner of the council's 40-acre estate. The building is of brick construction, with a copper roof. In form it consists of a central block with two obliquely set wings at each end—an arrangement which provides excellent light in all rooms. The centre block is of seven storeys and the wings are of three storeys, from ground level at the front. The total area of the working space is approximately 90,000 sq. ft., excluding the Fletcher Memorial Hall (at the rear of the main block) and stores. Separate buildings are being constructed for an insectarium and for work on radioactive isotopes.

The general arrangement is as follows: lower ground floor, engineering services, stores, and laboratories; ground floor, administration, fine-instrument shop, and laboratories; first, second, and third floors, laboratories and animal-house; fourth floor and mezzanine, library; fifth floor, canteen; sixth floor, club rooms.

The building is notable in several ways. Thus in the chemistry department the separate laboratories have no entrance doors, and instead open on to a central aisle; while in the biophysics division all the darkrooms (for electron microscopy, photography, &c.) are placed centrally, thus ensuring the best use of window space for lighting. There are hot and cold rooms on each floor, and the largest of the cold rooms is equipped for laboratory work. In the animal-house the cages are slung from the ceiling, thus affording free access.

The division which has perhaps gained most by the transfer is that of biophysics, which at Hampstead was both cramped and scattered. This department epitomises the spirit of integration which the council has set out to foster, for at least half the time of its workers is devoted to services to other workers in the institute and elsewhere. The division undertakes all forms of microscopy: and it contains an electrophoresis laboratory, a counting-room for radioactive isotopes, and a mass spectrometer laboratory. (In the past two and a half years the mass-spectrometer, built by the institute staff has been used for 1500 analyses a year.) The division also undertakes the freeze-drying of biological materials; and it is equipped for ultrasonic disintegration. There is a subunit of photography. The service provided here is probably unparalleled by any other single department in the world.

When the transfer to Mill Hill is completed, the Hampstead building will not be abandoned. It is to house some of the council's scattered units.

PROVINCIAL TEACHING HOSPITALS

BOARDS OF GOVERNORS

THE Ministry of Health has made the following appointments, mainly to fill vacancies caused by the retirement in rotation of a third of the members, to the boards of governors of the ten provincial teaching hospitals in England and Wales. Of 89 appointments, 69 are reappointments of retiring members. There are two appointments outstanding. The names of the medical members are shown in bold type.

UNITED NEWCASTLE-UPON-TYNE HOSPITALS

Reappointed: **H. H. Evers**, F.R.C.O.G.; Prof. **F. J. Nattrass**, F.R.C.P.; Prof. **R. Bramble Green**, F.R.C.S.; E. F. Collingwood, C.B.E., J.P.; T. A. Wright; Alderman John Chapman; Edward Colgan; F. B. Fenwick; John Walmsley.

UNITED LEEDS HOSPITALS

Reappointed: Alderman David Beevers, J.P.; Prof. **A. M. Claye**, F.R.C.O.G.; Prof. **T. Talmage Read**, F.R.F.P.S.; Prof. A. N. Shimmin; W. M. Jones; Miss Elinor Lupton, J.P.; **J. E. Rusby**, M.C., L.M.S.S.A., J.P.

New member. **Donald Watson**, F.R.C.S.

UNITED SHEFFIELD HOSPITALS

Reappointed: A. R. Martin; J. I. O. Masson, M.B.E.; Theophilus Pearson, J.P.; **H. R. Vickers**, M.R.C.P., J.P. Prof. **E. J. Wayne**, F.R.C.P.; Albert Barber, B.E.M., J.P.; J. Madin, J.P.; Percy Malby.

New members: Councillor Albert Wilde; Lieut.-Colonel N. G. Pearson, D.S.O., M.C. (until March 31, 1951).

UNITED CAMBRIDGE HOSPITALS

Reappointed: E. W. Plumpton, J.P.; **C. H. Whittle**, F.R.C.P.; Prof. **A. Leslie Banks**, F.R.C.P.; Lady Bragg, J.P.; Mrs. Ethel Hepher.

New members: Lady Rook; T. C. Wyatt; E. C. Webb, PH.D.

UNITED OXFORD HOSPITALS

Reappointed: Miss Rosemary Spooner; **C. W. Carter**, B.M.; **R. G. Macbeth**, F.R.C.S.E.; **Arthur Elliot Smith**, F.R.C.S.; Alderman Mrs. **I. D. Harrison-Hall**, M.B., J.P.; A. F. King.

New members: J. E. Grant; R. E. Warrell; Colonel Krabbe.

UNITED BRISTOL HOSPITALS

Reappointed: Prof. **A. I. Darling**, M.R.C.S., M.D.S.: Alderman J. J. Milton, J.P.; Sir Philip Morris, C.B.E.; **A. G. Palin**, F.R.C.S.E.; H. B. Stokes, M.B.E.; Lady Sinclair; Councillor Mrs. Helen Bloom; Miss I. M. Lobb.

New member: T. H. Lawley.

UNITED CARDIFF HOSPITALS

Reappointed: Alderman Joseph Dicks; Sir **Ewen Maclean**, F.R.C.O.G., J.P.; Alderman James Griffiths, J.P.; S. R. Marsh; E. E. Tompkins, J.P.; A. S. W. Johnson, J.P.

New members: Alderman J. J. Panes, O.B.E.; **David Ioan-Jones**, F.R.C.S.; **William Phillips**, F.R.C.P.

[Associated Press

A biochemical laboratory.

for initiative. I am myself convinced that, for the organisation of work on problems requiring coöperative effort for their solution—and this includes many problems of medical research as it has developed today—these are the correct principles. . . . If the organisation . . . seems to some to be ill-defined and loose in structure, this is because of the pre-eminent importance which is attached to the principles of flexibility and avoidance of departmentalisation."

DIVISIONS

When the institute first opened, its work fell into three main divisions—bacteriology, pharmacology and biochemistry, and applied physiology. Down the years there has been increasing emphasis on biochemistry and biophysics on the one hand, together with a broadening of biological research through endocrinology to more general aspects of experimental biology on the other; and today the broad categories are physiology and pharmacology, pathology, chemotherapy, biochemistry, experimental biology, and biophysics. In each of these fields workers at the institute have contributed fundamental advances.

[Keystone Press

Sterile chamber.

The physiological work is associated chiefly with the name of Sir Henry Dale, O.M., the first director, whose research has ranged from studies of anaphylaxis to the work on chemical transmission of nervous impulses for which he was awarded the Nobel prize in medicine in 1936.

The present-day use of curare and allied drugs in anæsthesia largely derives from work of chemists and pharmacologists at the institute. In pathology the principal advances have been concerned with pathogenic viruses. These include the identification of dog distemper as a virus disease and the discovery of a method for its prevention; and the isolation of the influenza virus.

[Keystone Press

Cultivation of influenza virus.

In chemotherapy the foundation was laid for the development elsewhere of stilbamidine; while in pure chemistry a theoretical contribution led to fundamental clarification of the problem of the structure of steroids. The isolation of calciferol and its identification as the substance responsible for the antirachitic activity of irradiated ergosterol was the work of a team at the institute; and the division of experimental biology has done important research on problems of the physiology of sex hormones. On the physical side ultraviolet microscopy has been greatly developed; and the institute's workers now lead in the application of electron microscopy to bacteriology and virus research.

confused recollection of being in a small ward where something amused me very much. That night I lost consciousness for about a week. I was found to have a fractured skull. When I came to, I could read a little but could not speak or even grasp what was said to me. After I had been some days in this state the matron came in on her morning round and said as usual, "Good morning, Doctor," to which she was delighted to hear me reply, "Good morning, Matron."

My senses of smell and of taste were severely affected for about six weeks after this fall; most of the food tasted peculiar and not very appetising. Swede, a one-time favourite of mine, I still cannot eat; even other vegetables cooked in the same pot taste of it, and a most unpleasant taste it is. At first I could not enjoy the taste of whisky, and both beer and stout tasted like water. Luckily I have since fully recovered my taste as far as drinks go.

I went back to my job, but after about three months my epileptic fits were obviously becoming more frequent, so I had to resign. I returned home, hoping that the better food would have the same good effect as before, but I gradually got worse and developed some new symptoms. One was a greatly increased sensitivity to noise, so that the barking of dogs would upset me badly. When their noise was more than I could stand I used to dash out into the street to try and stop them barking. Usually, of course, by the time I got there they would already have stopped. There was also a curious tendency to lacrimate for no particular reason, and without the usual emotion. But I also had become more emotional, and was much more easily moved by sad passages in films or novels. My memory had got very bad. I had to write down any instructions or messages to the most minute detail. Here, for example, are the instructions in my notebook for finding the materials for making tea. "Teapot in cupboard facing one in kitchen. Milk in frig. 5 teaspoonfuls of tea. Sugar, find." This loss of memory made my everyday life more difficult. Thus, travelling across London by Underground, I put the ticket in my pocket, but when I had to produce it for the collector I could not find it and had to pay the fare again. I must have looked several times in the wrong pocket, and of course later on I found it easily.

My fits were by no means always complete. They often stopped at a stage when I was making involuntary repetitive noises. Once when out for a walk I went through the pedestrians' wicket gate at a level crossing and noticed that the spring was rather stiff. I said to myself, "That spring is too stiff" and then my thoughts, so to speak, "stuck," so I went on thinking "that spring is too stiff," "that spring is too stiff," as if my brain was a gramophone and the needle had stuck in the groove.

Another occasional trouble was the failure of my subconscious mind to make the subsidiary decisions—for instance, when writing something down I had to stop and think out all the separate actions, instead of occupying my mind entirely with what I intended to write. There were also curious variations in appetite. Once I had three breakfasts one morning and still had an excellent appetite for lunch. Another symptom is difficult to describe. On going back to revisit a once-familiar scene, some people are conscious of a difference in the atmosphere. Everything is in its familiar place and looks the same as expected, yet there is a different feeling about it all. I used to notice this difference of "atmosphere" or "background" nearly every day, sometimes for a week at a time. I even noticed myself how stupid I was becoming.

I was then fortunate enough to visit a neurological surgeon, and after a consultation with one of his physician colleagues I was admitted to a world-famous hospital. Here I had a more detailed and complete examination than ever before, and in a few days my cerebral tumour was found. I was very pleased, for I had never been satisfied with the diagnosis of idiopathic epilepsy. The tumour—an astrocytoma—was successfully removed a few weeks later.

In the seven months which have elapsed since the removal of the tumour my initiative has greatly improved; my intelligence has become keener; and I have had no grand mal attacks. I am still taking phenobarbitone twice a day. I still have occasional attacks of confusion or failure to find the right word, and sometimes a spell of acute depression lasting a few seconds. These attacks are unquestionably becoming less frequent, and altogether I am much more cheerful than I had been for several years.

Public Health

Dysentery in England and Wales

NOTES EXTRACTED FROM A MEMORANDUM BY MEDICAL OFFICERS TO THE MINISTRY OF HEALTH

THERE have been 3938 notifications of dysentery in the first quarter of this year, and the great majority of these cases were due to infection with *Shigella sonnei*. In comparison, the figure for the first quarter of 1945 (the year with the highest recorded incidence) was 5163. The average of weekly notifications for March, 1950, was 367, compared with an average of 208 for the same month in the eight-year period 1941–1948; while in the week ended March 25 notifications numbered 427—an incidence exceeded this year only in the last week of February (445). In such circumstances it is possible that the present year, after four years of comparatively low incidence, may prove comparable to 1945.

The largest numbers of notifications have been in the North; and up till now the West Riding of Yorkshire has headed the list, with the county boroughs, particularly Sheffield, as the main contributors. Notifications in Durham, Northumberland, and Lancashire have also been high.

In recent years the greatest numbers of cases have been reported in February, March, and April, and in September and October. Notifications in the other months of the year have not been immaterial, but curiously enough the hot summer months have had low figures.

Geographical distribution is remarkable in that some counties have notified practically no cases; and since Oct. 1, 1949, Bucks, Dorset, Hereford, Herts, Northants, Rutland, Salop, Somerset, Westmorland, Wilts, and all the Welsh counties except Carmarthen, Glamorgan, and Monmouth have produced less than 10 cases apiece.

The extent to which these low figures are due to failure of notification is uncertain.

Detailed analyses are not available, but there is little doubt that the distribution of cases by age-groups is much the same as previously, and that the 0–5 age-group is sustaining the main weight of the attack. As before also, day-nurseries and nursery schools and classes have suffered particularly, although intra-family spread has been very evident.

Clinically, the disease is mild, and the death-rate has been negligible. Nevertheless, concern is justifiable on account of: (1) the week or more of lowered health after the attack; (2) the occasional severe case, and, rarely, the death of a patient; and (3) the effect on industry of absence from work of large numbers of mothers who have to remain at home to tend their sick children instead of leaving them in the care of day-nurseries, nursery schools and classes, or similar institutions.

SOURCES OF INFECTION AND INFECTIVITY

The fæces of the frank case are an obvious source of infection, but convalescents, symptomless excretors,

UNITED BIRMINGHAM HOSPITALS

Reappointed: Alderman A. F. Bradbeer; D. Bulgin; Prof. **P. C. P. Cloake,** F.R.C.P.; J. F. Crowder; Alderman Mrs. Elsie Farley, J.P.; Sir Raymond Priestley, M.C.

New members: **Ernest Bulmer,** C.B.E., F.R.C.P.; W. J. G. Sperryn; H. Busill Jones.

UNITED MANCHESTER HOSPITALS

Reappointed: **O. M. Duthie,** M.D.; Alderman Joseph Eastham, J.P.; E. C. C. Evans, M.B.E.; G. H. Goulden; Graham Halbert; Prof. **H. S. Raper,** C.B.E., F.R.C.P., F.R.S.; **Sir John Stopford,** F.R.C.P., F.R.S.; Prof. **F. C. Wilkinson,** M.D., F.D.S.

New member: H. S. Newbold.

UNITED LIVERPOOL HOSPITALS

Reappointed: Sir **Henry Cohen,** F.R.C.P., J.P.; Miss Mary Jones, O.B.E.; Thomas Keeling, J.P.; George Leather, J.P.; Thomas McDonald; Prof. **H. H. Stones,** M.D., M.D.S.

New members: Councillor H. S. Dickson; Councillor W. L. Bateson; **Philip Hawe,** F.R.C.S.

Disabilities

50. CEREBRAL TUMOUR

WHEN I was a boy of 15 or 16 I had an attack of malaise, ushered in by the most severe headaches I have ever had. The local doctor ordered me a mixture which stopped the headaches though the malaise continued for another fortnight. I think it was at this time that I saw bright spots moving about rapidly for an hour or so, with no associated pain or other discomfort.

My progress at school was uneven. I entered for the junior-grade intermediate examination when I was a year under age, and unexpectedly passed. Next year, being the right age, I went up again, and failed. My school reports often said "Could do better"—but I don't regard this as at all diagnostic! Next year I unexpectedly passed the middle grade. When I entered college I took my place at the tail of the brighter ones, or at any rate in the van of the ruck. However, I did not manage to keep this up for more than a year or so.

For many years after this I had vague symptoms which I did not take very seriously. It is so difficult to know what is the normal. From time to time I would lose my appetite, and I used to sweat a lot, especially on exertion, so that a bunch of keys in my trouser pocket was usually rusty. Occasionally I noticed the little and ring fingers of my left hand twitching, and now and then I had a feeling that some disaster was about to happen. Sometimes I was irritable, and sometimes I made caustic remarks; but many of us do.

When I was abroad, at the age of 35, I had a more severe attack of malaise, accompanied by bradycardia and giddiness, and shortly afterwards I had my first epileptic attack. In the middle of the night I was awakened by a pain in my back so severe that I had to take opium for it. In addition, my tongue was sore and my pillow bloodstained. There was no enuresis in this attack or in any subsequent one. When consulting my doctor about my back I mentioned the question of epilepsy, but he did not take the suggestion very seriously. Later my back was X-rayed and a deformity was found; I was admitted to hospital, where the final diagnosis was Scheuermann's disease. (This is of the same nature as Schlatter's disease, but in a different site.) While I was in hospital I noticed an occasional sinking feeling in the precordium, followed by a forcible heart-beat, and this symptom continued intermittently up to a few weeks ago.

About nine months after my first fit I had several more at night, and as these were noticed by other people a diagnosis of idiopathic epilepsy was made. The attacks now assumed a pattern: they nearly always occurred at night; I nearly always injured my tongue, but was never incontinent; and my muscles were always stiff afterwards. Sometimes my appreciation of colours and sounds was heightened after the fit.

Up to this time my mind had been pretty clear; but now I began to have a peculiar sensation as though my thoughts were being rapidly revolved. I could almost hear the buzz! This happened many times a day, but it was all over so quickly that it caused me little inconvenience and did not interfere with my usual activities; my train of thought continued its course practically uninterrupted. I also noticed that if I was in a brightly lit room and the light was suddenly put out, there was a subjective image of brightness which flickered about 10 times a second for several seconds. Later I lost the bright image which normally follows pressure on the eyeball—"seeing stars." I was on a poor diet, so I went home to Ireland and enjoyed unrationed food for a few months, with excellent results; I put on weight rapidly, my psychological symptoms disappeared, and I soon felt quite well. So, taking the optimistic view, I decided that the whole thing was a matter of malnutrition, and returned to work.

I now had to live in lodgings, and the war-time diet there was very poor. About two months after I had resumed work I had rather an alarming experience. While walking with some friends I suddenly felt as though a flash of lightning had passed through my brain. I did not tell anyone about it—indeed, I had become rather secretive about the whole business. A few weeks later I had a similar attack. About this time I had nocturnal cramps in my calf muscles, and I often found difficulty in emptying my bladder at one go; sometimes it took several attempts, each producing some urine, before the bladder was empty. A few months later I began to have trouble with my eyesight. I had my eyes tested and wore the glasses ordered even when using a microscope; they gave me some relief.

I now had my first epileptic attack when not in bed. I was talking to a colleague when I suddenly had the most awful feeling of terror I have ever experienced. The whole world seemed to be slipping away, leaving me isolated and helpless. When I came to, I found myself on a stretcher on my way to a ward. When I was better I went to a well-known hospital and had the routine investigations for such a case; the diagnosis was as before—idiopathic epilepsy.

Then I began to have more severe psychological symptoms. The moving lights recurred, though they did not last so long as before. Several times I felt an urgent desire to speak to anyone who happened to be close by, whether I knew them or not; I did not know what words I wanted to say, so the result was an intense mental conflict. Occasionally, after I had gone to bed, I had a feeling of acute loneliness, almost amounting to fright. In the daytime I sometimes used to sit at my desk gazing into space for long periods, unable to concentrate on my work. If I suddenly stood up, I had peculiar feelings which I cannot describe, lasting a second or two. Sometimes the same thing would happen just before I yawned. I also noted that when I took off my hat the rim left a horizontal mark on my brow which remained visible for an hour or more.

For domestic reasons I had to return home, and the day after I got back I went down to the village to make some purchases. I can remember walking out of a shop, but just after that I must have fallen heavily, striking my head such a resounding crack on the pavement that the shopkeeper came running out to see what had happened. I was taken to hospital on the fire-engine, which happened to be there at the time, and apparently I could speak on arrival, as I gave my name and address correctly. I cannot remember that part, but I have a

This appears to be the most serious outbreak of the disease since 1943, when 7007 cases occurred in Calcutta. Normally, the Calcutta curve of incidence falls off sharply in July and August, with the coming of heavy rains. During the past thirty years, the annual number of cases in Calcutta has never fallen below 1800.

Apart from the seasonal rise in incidence, the influx of refugees appears to be a factor in the present outbreak.

Parliament

Quality of Flour

On April 20 and 25 the House of Lords discussed whether the extraction-rate of our flour should be decreased from 85 to 80%. In moving for papers Lord **Hawke** called attention to the unsatisfactory quality of our present flour. It produced a dirty-coloured bread which did not keep, did not taste good, was indigestible, and required adulteration. For all this he blamed the high extraction-rate. Before the war we had an extraction-rate of 70 to 72%, producing a white bread which was acceptable to the people. In the war to save shipping the rate was put up to 85% and was subsequently reduced to 80%. In 1945 a strong committee, of which Lord Horder was a member, considered the question of the post-war loaf and recommended an 80% extraction-rate. The committee considered that a lower extraction-rate would be nutritionally satisfactory provided that it was fortified, but this the medical members of the committee were not prepared to recommend without having the results of further experience and experiments. In May, 1946, the extraction-rate was put up to 90% as a result of a world wheat shortage, but in September of the same year the rate was reduced to 85% and it had remained at that level ever since.

Owing to the higher extraction-rate, he continued, there was more phytic acid in the flour, and to offset this it was necessary to add some chalk-like substance, which was unwelcome to many. Lord Hawke held that the time had come to revert to an 80% extraction-rate, and indeed even a lower rate in the light of experiments on fortification.

Lord **Horder** said there should be made easily available for every citizen the best bread that modern milling and baking could produce. By "best bread" he meant a bread that contained a maximum amount of essential nutrients compatible with acceptability of taste, colour, texture, and digestibility. Digestibility had been specially considered and they had come to the conclusion that provided a patient could eat bread at all, he could eat and digest the national loaf—i.e., the 85% extraction loaf—equally as well as the pre-war loaf. But acceptability was important for two reasons. If bread was acceptable it was digested better and more was eaten. Also, if bread was acceptable less was wasted. The idea that bread was just a starchy food was a fallacy; it was good and a cheap source of protein as well as of other essential nutrients. It was, and deserved to be, the staff of life, and millions of our people depended on it as their main source of nutrition.

Lord Horder agreed that the interdepartmental committee set up to assist the Health, Food, and Supply departments in advising Ministers on regulations to be made when war controls were removed, had come to no decision as to the relative value of a low extraction-rate with enrichment as against a high extraction-rate without enrichment. Lord Horder thought that conclusion was wise, because knowledge of those matters at that time—in 1945—was inadequate to justify a decision. The committee had recommended an extraction-rate of 80%, which was the rate current when it met. Lord Horder asked why we should not now return to that rate, which gave a more acceptable loaf and adequate nutritional value.

Finally, Lord Horder uttered a warning against attaching too rigid a significance to the extraction-rate [illegible] when assessing the nutritive value of bread. [illegible] departmental committee had urged that further [illegible] should be undertaken, and Prof. R. A. [illegible] F.R.S., and Miss E. M. Widdowson, PH.D., had recently undertaken tests on behalf of the Medical Research Council in which groups of German children were fed with bread of 100% extraction, with bread of 85% extraction, with pre-war bread of 72% extraction enriched with vitamins, and with pre-war bread without enrichment. Each child had as much bread as it wished, and its normal ration. When the experiment began the children were all about a year behind American children in weight and one year and four months behind in height. After nine months the children had about caught up to the American standards, but in Dr. Widdowson's own words: "There was no difference whatever between the five groups . . . the children on unenriched white bread did as well as the others."

But Lord Horder added the warning that an experiment must not be taken out of the conditions in which it was made, otherwise the interpretation might be fallacious, and Professor McCance and Dr. Widdowson had definitely stated that their results applied only to the conditions in which the experiment took place. Lord Horder quoted these experiments to show we were only on the threshold of the science of nutrition. He believed it was time that the important matter of the bread of the people should be re-surveyed. He hoped that the post-war interdepartmental committee would meet again soon to consider a full report of this important work by British researchers.

Lord **Teviot** agreed that the present loaf was abominable and its keeping quality appalling, but revealed himself as a supporter of the 100% extraction loaf. Lord **Hankey**, who also supported a high extraction-rate on grounds of health, asked whether agenising of bread was being continued.

Lord **Llewellin** affirmed that it was one of his aims when Minister of Food to see that 100% extraction-rate bread was available all over the country. He himself much preferred it to the 85% extraction-rate bread. But it was clear that if the choice was left to the consumers they would prefer a whiter and less soggy loaf. The Board of Admiralty had always resisted the requests of the Ministry of Food to use a higher extraction-rate bread, and he had not noticed that the health of the Navy had deteriorated while the personnel had been living on 72% extraction-rate bread. It was easier to make good bread out of an extraction-rate flour of 80% than out of flour of 85%, and there was little doubt that with an 80% extraction-rate all the necessary nutrients could be retained.

Viscount **Alexander of Hillsborough**, Chancellor of the Duchy of Lancaster, replying for the Government, said that a large proportion of the charge for the extra wheat required to lower the extraction-rate would have to be met in dollars. A second important consideration was whether the extra milling offals would be dearer than imported feeding-stuffs. No decision had been taken by the Government about the permanent extraction-rate. The Minister of Food would consider the suggestion that he should re-convene the conference on the post-war loaf. A special subcommittee had been appointed to examine what progress had been made in investigations recommended by that conference. There had always been a waste of bread, but there was no evidence that the waste was greater now than before the war, and better use was being made of waste as feeding-stuff. It was possible that the level of the extraction-rate had contributed to the great improvement in the nation's health, but because increased food-supplies were now available the rate might be altered without lowering the average nutritional intake. Recent evidence had become available of the possible toxic effects of the commonly used improver 'Agene.' A committee on which the Medical Research Council was represented had recommended that in future chlorine dioxide should be used. This recommendation had been adopted in the United Kingdom but it would take a little time to change over the necessary plant to give effect to the new decision. Calcium was first added to bread in 1942 to offset a serious deficiency of that item in our diet which had been well-known to nutritional experts before the war. Even with the better diet we now had, the nation as a whole would not get enough calcium without this addition to their bread. The amount added was 14 oz. per 280 lb. sack. Within and other undetected and mild cases, especially in children, are probably the greatest danger, in that they may continue to excrete the organism for some weeks, and often intermittently. Chronic carriers are probably not as important an epidemiological factor in the spread of this disease as the more temporary excretors.

Adults and adolescents are not as great a risk to the community as children, but they can be dangerous as sources of infection when employed as food-handlers or in the care of young children, and particularly when their personal hygiene is not all that it should be.

The infectivity of *Sh. sonnei* is very great, and there is little doubt that comparatively few organisms are required to initiate infection in a child. The disease can in fact be classed with such highly infectious diseases as chickenpox and measles.

NOTIFICATION

Notification is an important feature in prevention, and reasonable accuracy is essential. The term " dysentery " comprises not only, as in the past, fatal cases and those severe enough to be notified on clinical grounds (usually the presence of blood and/or mucus in the stools, and tenesmus) but also any cases of diarrhœa in which the medical practitioner has reason to believe, on epidemiological or clinical grounds, that the infection is dysenteric, as well as those mild and even symptomless cases diagnosable by laboratory methods only.

Notification should always be practised on this basis, and the procedure should not vary in different areas. The fact, moreover, that a case is mild should not, in view of the danger to the community, be used as an argument for non-notification.

TRANSMISSION

The infection may be ingested with aliments contaminated directly or indirectly by individuals handling them, or through eating and drinking utensils similarly infected. Flies and dust may also at times spread the disease. Probably, however, greater importance than at present should be attached to the spread of infection by direct personal contact between children, as well as indirect through the medium of communally used toys and other articles. It is not unlikely that hand carriage of the organism is, in such circumstances, the chief operative factor. Adults, too, apart from possibly infecting food and feeding utensils handled in the course of their duties, may at times act as direct mechanical carriers of the disease to children with whom they deal.

DETECTION

In a disease so highly infective as Sonne dysentery and with such rapid spread, speedy recognition is vital. Clinically the signs and symptoms, varying widely according to the severity of the infection, are well known. From the bacteriological point of view, laboratory confirmation of a suspected case is very important, and a stool specimen should be sent at once with this end in view.

In institutions a rectal swab gives the best results, but this must reach the laboratory within 4–6 hours. This method, however, has the disadvantage that the specimen can only be taken by a medical officer or qualified nurse or health visitor, and thus difficulties arise when the disease is very prevalent. The ordinary stool specimen is often satisfactory, though care must be taken to prevent contamination of specimens from imperfectly sterilised chamber pots. The specimen should reach the laboratory within 24–48 hours. Laboratories can report the results within 24 hours with practically complete accuracy. The importance of examining fæcal specimens from contacts, or indeed from members of infected closed or semi-closed communities, will be appreciated in view of the large numbers of symptomless excretors in many outbreaks of Sonne dysentery. Outside such communities, however, this action is unlikely to be profitable except in special circumstances.

Much still remains to be learned about the natural history of Sonne dysentery.

The number of consecutive daily negative stools necessary before bacteriological cure can be guaranteed is not precisely known ; but a minimum of twelve has been suggested. However, it is usually impracticable to continue clearance tests beyond three consecutive daily negative stools.

CHEMOPROPHYLAXIS

For prevention reliance must continue to be placed chiefly on the old and tried methods applicable to any disease where the source of infection is the fæces of the case or carrier.

Chemoprophylaxis must be secondary to basic preventive measures. Here succinylsulphathiazole *B.P.*[1] is the drug of choice ; absorption of this from the bowel is only slight, and thus the risk of producing sulpha-resistant strains of streptococci and other organisms elsewhere in the body is minimal. Sulphaguanidine offers this same advantage but is possibly not quite so efficient. In infected semi-closed and closed communities there is much to be said for the mass application of sulpha-prophylaxis. In this way the delay while awaiting laboratory reports is averted. Furthermore this method overcomes the difficulty that excretion of the bacillus is often intermittent.

The suggested dosage of succinylsulphathiazole for children 2 years of age is 4 g. daily—2 g. with breakfast and 1 g. at each of the two other meals—for one week ; the dosage is greater, according to age, up to 6 g. for adults. The course may, if necessary, be repeated once or twice with an interval between courses of one week. Apparent failure of sulpha-prophylaxis may often be due to reinfection, and contact of children, after chemoprophylactic treatment, with possible excretors or carriers should be avoided as far as possible.

Most children become non-infective within a week or two of the attack ; but a few may continue to excrete the organism for several weeks, and persistent excretors of this sort may have to be segregated. There is need for further research into the efficacy of sulpha-prophylaxis.

Vital Statistics for 1949

The following provisional death-rates per million population for England and Wales in 1949 are recorded in the Registrar-General's return for the week ended April 22 :

	Males	*Females*	*Persons*
Tuberculosis :			
Respiratory	516	301	403
Non-respiratory	62	47	54
Cancer	1981	1771	1871

The maternal mortality (provisional) per 1000 total live and still births, based on deaths primarily classed to diseases of pregnancy, childbirth, and the puerperal state as arranged in the Manual of the International List (5th revision) was as follows : Postabortive infection, 0·11 ; abortion without mention of septic conditions, 0·05 ; infection during childbirth and the puerperium, 0·11 ; and other maternal causes, 0·71.

Cholera Outbreak in Calcutta

According to information reaching the headquarters of the World Health Organisation, cholera morbidity and mortality have been steadily rising in Calcutta since early March. In the first fifteen weeks of 1950—i.e., between Jan. 1 and April 15—3311 cases and 1233 de[illegible] were reported. In the last four weeks—i.e., March 19 and April 15—1768 cases and 705 d[illegible] reported.

In England Now

A Running Commentary by Peripatetic Correspondents

When I was doing a locum at Market Citron last summer I got a message by the carrier to say that Mrs. Frost's little girl, aged three, at Snoring Virginibus (not to be confused with Lower Snoring) had swallowed a threepenny bit. As the carrier had a long round I didn't get the message till the day after the alleged swallowing. When I went into the village shop to ask where she lived there was a woman being served and a little girl fondly handling some cube dog-biscuits in an open sack. When I asked where Mrs. Frost lived this woman replied, "I am Mrs. Frost." I asked whether it was her little girl who had swallowed the threepenny bit. "Yes," she said, "one of them new ones with three balls on it." "Is she all right?" I asked. "Yes," was the reply, "she's all right, but she can't swallow." So without leaving the shop I rang for a Bevan Bus to take her to Eastwich, twenty miles away. In due course I got a chit: Coin removed, œsophagoscopy, at level C7–T1, just below upper end of œsophagus."

Now I feel we ought to have tables to show what coins can be swallowed at what ages. Here, for instance, 3d. into 3 just won't go. Years ago when I was going round a mental hospital a most lovable man with mania said, "Do lend me tuppence." I did so, and he promptly swallowed it. In an awful funk at my criminal carelessness I dashed him off to the X-ray room, where to my enormous relief we found he had a sort of Wallace collection inside; my pennies were indeed small change. I think we can safely say even half-a-crown goes into a maniac easily.

We peripats ought to be able to make up fairly comprehensive tables—for all the orifices.

* * *

I am tired to death of well-bred pictures. Good taste in art seems to me much more dangerous than vulgarity because it can slip so easily into polite death, while vulgarity is at all events alive and full of zest. I suppose Laura Knight's painting of Princess Elizabeth at the rebuilding of Coventry, in the Summer Exhibition at Burlington House, is a thoroughly vulgar picture. The figures are arranged as though for the footlights, with the Princess in the middle. Her gay yellow dress is set off by the robes of the Mayor and Council, and the Mayor has been caught in a moment of excitement and gesture at once lively and theatrical. This is surely going to be a historical picture which will give pleasure for many a generation to come; and need a historical picture do more? Actually it does do more: it shocks your taste and makes you laugh, two excellent things at the Royal Academy; and it displays all the technical accomplishment of Dame Laura's work. A different sort of pleasing vulgarity turns up in James Fitton's "Les Girls," three elderly and rakish ladies chatting in dashing colours over a pint. The same quality helps to make the charm of Leslie Cole's "Local Conversation," and Steven Spurrier's "Music Hall"; and I suppose that the characters in Stanley Spencer's "Resurrection," if not exactly vulgar, are on the whole pretty common: it would be hard to be less on resurrection morning. They have very much the look of people coming out of air-raid shelters, except that they seem much fresher and are moving so fast; one wonders how he kept them still long enough to paint them.

"Children at Chess" by Mary Sargant Florence is not at all vulgar—a brownish picture and rather plain children, but unusual. You *could live with it for* good, which is more than can be said for the other three: and in a way we shall have the chance, because the Royal Academy have bought *it under the Chantrey* bequest. But if I could choose pictures to live with I think I should always choose pen-and-wash drawings—like Margaret Shaw's "Interior," or her white hung "Bed"; or perhaps George Bass's "Greenwich Figureheads"; or perhaps chalk, and indian ink like Frank Dobson's "Secretary Bird"; or perhaps a lithograph like Hilary Edwards's "Dancing Class." I don't think I would choose sculpture: not, at any rate, this socking great Lady Godiva by Sir W. Reid Dick, and still less "The Sixth Day—project for colossal group" by Maurice Lambert, where the cover of "Punch" seems to have got into three dimensions with intent to cap some colossal wedding cake.

* * *

"RE POST OF PATRIOTIC REGISTRAR STOP PLEASE STATE WHETHER . . ." ran the wire.

And yet, why not a patriotic registrar? He is, I submit, a wholly credible figure: a bit shaky, perhaps, as a clinician, but ever watchful for subversive trends in the house staff or anarchy in the students; and *undoubtedly one of those worthies whose qualities were* listed by Noel Coward: "Upright. Straightforward. Downright." I feel the management committee have *defined a need. Let there be patriotic registrars*—at least one per thousand beds.

Or do they want a patriotic pædiatric registrar? If so, then they will have to search far and wide. There is something in the practice of pædiatrics which drives out the nobler virtues. Faced with the low cunning of the young, one ultimately takes the hint and stoops to the same level of duplicity—"Only a little prick, Johnny. You'll *hardly feel it at all*"—and I, for one, doubt whether the coefficient of patriotism is high in the pædiatrician; well, not so high as in, say, your neurosurgeon or your venereologist.

Anyhow, good luck to them. Theirs is a strange and altruistic quest. May they find their patriot, cherish him, and pay him well.

* * *

I am very sleepy and hungry, so I have cooked myself an omelette and taken it to bed. Propping myself on one elbow I jab it with a fork in one hand and with the other turn over the advertisement pages of THE LANCET. There is a picture of a bony fish with a profound statement above it. I feel sure it would mean *something* if I wasn't half asleep. I turn on to the small advertisements at the end. Someone is selling an electric chair. *Funny thing* to have. Might be useful if one was contemplating a private purge of one's acquaintances. It has its own charges. I see, so I suppose it is a portable for use in one's country house as well as in town. Or perhaps the charger is a horse, which carries the chair about on its back. And here is a man offering rabbits. He says that Friedman does a specialty. Is Friedman the first shaggy rabbit on record? What does Friedman do, exactly? Does he bat, like the shaggy horse, or play the piano like the shaggy frog? When I wake up again I see it says: "Friedman Does a specialty," which is a different matter. The next one is a snip for spivs. A thousand medical certificates for 21*s.* 6*d.* That seems very cheap. I have been offered more than that for *one*. But what is this? Doctor required for Tea Garden Practice. That sounds languid enough to suit me. Pay is a minimum of 2100 Rs. per mensem. *Mensa, mensa, mensam,* surely. How many Rs. to the pound? Or is it pounds to the Rs.? It is all much too confusing. I lay my head on my omelette and go to sleep.

* * *

An 82-year-old gentleman recently walked into a doctor's surgery in this neighbourhood with a knife protruding from behind the angle of his jaw. After removing the knife, which had penetrated 4 inches, the doctor admitted him to our hospital where his wound was sutured. No damage had been done to the vital structures in the neck. He seemed a kindly old man and very active and intelligent for his age. He explained that his 72-year-old wife had stabbed him, but he was apparently quite unconcerned on this account, since she had been attacking him with knives, tin-openers, and other sharp instruments every week or so for the last three years. His forearms and hands were consequently covered with scars of all shapes and sizes. The reason for her unusual behaviour, he said, was that some fifty years ago he had at times gone off with other women, and she was now getting her own back. He didn't seem to have thought of leaving her (as he easily could have done, having numerous children in the district). When she first began to attack him he took counter-measures: but in recent years he had not bothered, for he was an old soldier who had been through several wars and had thereby become accustomed to discomfort and danger.

the limits of the economic situation the Minister of Food would wish to give weight to the remark quoted by a noble Lord earlier in the debate: "a little of what you fancy does you good."

QUESTION TIME

Glasgow Smallpox Outbreak

Mr. JOHN RANKIN asked the Secretary of State for Scotland whether all hospitals in Glasgow and the West of Scotland were notified of the presence of smallpox contacts in their areas during the recent outbreak; and why the late Dr. Janet Fleming, while suffering from a virulent form of smallpox, was admitted in the ordinary way as a patient to Hairmyres Hospital, Lanarkshire, and remained there for three days under observation, during which period responsible medical authorities had in their possession official notification that she was a smallpox contact.—Mr. HECTOR McNEIL replied: It was the function of the medical officers of health to keep all known smallpox contacts in their areas under observation, and they would at once notify any hospital to which such a person was removed. As an additional precaution every hospital throughout the West of Scotland was informed by the Western regional hospital board immediately smallpox had been diagnosed in Knightswood Hospital, and they were asked to be on the lookout for possible secondary cases among new patients. Dr. Fleming was admitted to Hairmyres Hospital, suffering from a condition diagnosed as an acute abdominal one, on the morning of March 27 before anyone in Hamilton knew that she was a smallpox contact. As soon as it was known that she was a smallpox contact, the hospital authorities made special clinical and laboratory examinations. This evidence, I am assured, was thought to exclude a diagnosis of smallpox. At a later stage, however, the development of her illness indicated that she was suffering from an unusual form of smallpox and she was at once removed to the smallpox hospital, where unfortunately she died.

Mr. JAMES CARMICHAEL asked the Minister if he would examine the possibility of having all infectious diseases hospitals managed by the local authorities so that one authority would be responsible for the entire administrative duties necessary to combat and eliminate infectious diseases.—Mr. McNEIL replied: In the light of experience during the recent outbreak, I am reviewing the arrangements for cooperation between hospitals and public-health departments with particular reference to the control of infectious disease. I have, however, no reason to think that it is necessary to rearrange hospital services in the fashion suggested.

Vaccination of Hospital Staffs

Mr. L. D. GAMMANS asked the Minister if he proposed to make any investigation into the circumstances in which members of the nursing staff of the Glasgow isolation hospital contracted smallpox; and when each of them was last vaccinated.—Mr. McNEIL replied: The patient who was the primary source of infection was admitted to hospital suffering from pneumonia and the 8 nurses who contracted smallpox were direct contacts of this patient. From investigations which I have already put in hand I understand that of the 3 nurses who died none had been successfully vaccinated. The other 5, all of whom are recovering, had been vaccinated more than once, the last occasion being some years ago.

Mr. GAMMANS: When almost every country in the world insists upon vaccination before people are allowed to land, is it not quite fantastic that young women should be allowed to work in an isolation hospital with all the risks of nursing smallpox patients without being compelled to be vaccinated?—Mr. McNEIL: Of course there are two points to be made. First of all, these nurses did not know that the patient they were nursing in the first stage was a smallpox contact. I do not want to be thought hostile; I understand the hon. gentleman's concern. But we are experiencing difficulty in recruiting nurses and it would seem to me obvious that we should not impose on nurses a condition which we do not impose on the rest of the community.

Sir JOCELYN LUCAS asked the Minister what steps were taken in the fever hospitals under his control to see if vaccinations for smallpox were successful or not.—Mr. McNEIL replied: The normal procedure is that the doctor who has performed the vaccination inspects the result and if the vaccination has not been successful he repeats it. Records are kept of all vaccinations and re-vaccinations and their results so that the medical superintendents of the hospitals may have current information of the state of protection of their staffs. I am, however, reminding hospitals and local authorities of their appropriate responsibilities.

Fees for Vaccination

Mr. HENDERSON STEWART asked the Minister if he was aware that vaccinations were being carried out on a wide scale throughout Scotland, but that medical practitioners had not yet received any payment for this work, nor any indication of what payment might be offered: and if he would make a statement on the matter.—Mr. McNEIL replied: I am indebted to all medical practitioners who coöperated so zealously in vaccinating over the last few weeks. I am bound to point out, however, that vaccination is considered to be a normal part of good general practice, and so for general practitioners inside the National Health Service no special payment for these services is due. Negotiations, however, are in progress between the British Medical Association and the local-authority associations to secure agreement on a fee to be payable by the authorities for reports from practitioners giving particulars of vaccinations and immunisations carried out.

The Law of Coroners' Courts

Mr. ANTHONY MARLOWE asked the Home Secretary whether he was aware of the urgent need to introduce legislation to amend the law relating to coroners' courts; what steps he had taken consequent upon his undertaking of Feb 5, 1948, to look into this question; and whether it was intended to implement any of the recommendations on this subject contained in the report of the Lord Wright Committee made in 1935.—Mr. CHUTER EDE replied: Most of the recommendations of the Departmental Committee on Coroners could be implemented only by legislation. Although I have not overlooked the desirability of reviewing the law relating to coroners, I cannot promise to introduce legislation on this difficult and controversial question in the near future.

Earl WINTERTON: Is the Home Secretary aware that again and again, so far as it is possible to do so under the rules of the House, attention has been called to the fantastic anomaly of the present law and the extraordinary latitude allowed to these people? Why should he not bring in a Bill which provokes no party controversy, and which could be left to the discretion of the House to pass? Is he aware that two years ago he promised to give consideration to this most urgent question?—Mr. EDE: I have been giving consideration to it.

Mr. MARLOWE: Does not the Home Secretary agree that most of the controversy comes from the coroners themselves, and that it is in order to remove from them certain privileges, which they are trying to safeguard, that this House ought to act?—Mr. EDE: Coroners are also God's creatures.

Beds for the Tuberculous

Mr. H. L. D'A. HOPKINSON asked the Minister of Health whether his attention had been drawn to the increase in the number of cases of tuberculosis and the swing of incidence from persons aged 15 to 25 to those aged 45 to 75; and what action he proposed to take to accommodate chronic cases of persons in the latter age-group, who were at present often compelled to live in their own homes surrounded by children.—Mr. A. BEVAN replied: Notifications have increased through the use of mass radiography and other improved methods, but this does not necessarily imply an increased incidence. Every effort is being made to recruit staff for more beds.

Mr. HOPKINSON asked the Minister whether, in view of the lack of accommodation in tuberculosis sanatoria due to the shortage of nursing staff, he would undertake a special propaganda campaign to show that such sanatoria were less dangerous to the health of the nursing staff than ordinary hospitals.—Mr. BEVAN replied: I see no particular advantage in concentrating on this one aspect; but, with my advisory committees, I have the whole wider question under review.

Replying to Mr. SOMERVILLE HASTINGS, Mr. BEVAN gave the following figures for staffed beds in sanatoria on Dec. 31:

Number of staffed beds 22,815

Nursing staff	*Full-time*	*Part-time*
Trained nurses	1874	227
Enrolled assistant nurses	917	277
Student nurses	1186	—
Other nursing staff	918	498
	4895	1002

inducements of experience in other types of medical work and in many cases of research into unexplored fields, as well as the organisation of a unit.

It is to be hoped that some, at least, of the senior registrars who will otherwise be disappointed in the competition for posts as consultants will consider the alternative of employment in one of these capacities in the Services or in the Colonies as a career, and not only as a possible interlude until—an unlikely event—employment is available to them at home.

These posts should offer excellent professional opportunities, which may well tempt many, irrespective of their chances of appointment here. They are surely infinitely preferable to a period of waiting for the steadily diminishing chance of consultant posts at home, where the competition in the next two or three years must be extremely strong.

London, S.W.1. PHILIP H. MITCHINER.

THE THYROID AND HYPERSENSITIVITY

SIR,—The article of March 18 by Dr. Long and Dr. Miles would seem, at first sight, to provide good presumptive evidence that thyroxine enhances hypersensitivity to tuberculin in the guineapig, while, as would be expected, 'Cortisone' or adrenocorticotropic hormone peptide (A.C.T.H.P.) has the opposite effect. The results obtained are so clear-cut as to risk the wholesale acceptance of their implications. The following critical analysis in the light of recent research with which these authors are apparently unfamiliar may prevent any misconception regarding the rôle of the thyroid in hypersensitivity.

A most careful investigation[1] of the effects of thyroid feeding, thyroidectomy, and thiouracil on the histology and cytochemistry of the adrenal cortex has shown most clearly that, while thyroid feeding initially produced hypertrophy and signs of hypersecretion in the zona fasciculata, prolonged administration resulted in signs of exhaustion and cell degeneration, with the accumulation of large fatty droplets in many cells of this zone, in which recent evidence suggests most strongly that the sugar hormones are elaborated.[2] It would seem that the initial effect is hypertrophy and hypersecretion, and the late effect hypertrophy, exhaustion, and hyposecretion. This evidence is also supported by the observation that in human hyperthyroidism the corticoid excretion may be increased, normal, or decreased, and in a crisis reach the levels found in Addison's disease. In myxœdema the corticoid excretion was low, and increased in response to the administration of thyroid.[3]

Though Long and Miles state that the degree of hyperthyroidism induced was not severe, it is notable that two animals died with hæmorrhages in the cortex. In view of the large fatty droplets, mentioned above,[1] the photograph of the adrenals stained for cholesterol cannot be regarded as indicative of the state of cortical function, and no histological or cytochemical data are presented. It is therefore very probable that the increase in sensitivity resulting from the administration of thyroxine was not a direct effect of this hormone, but was indirectly due to cortical exhaustion, despite the grossly enlarged glands.

No effect was noted from the administration of propylthiouracil, but the dose was much less than that used by previous investigators,[4] who used thiouracil, not propylthiouracil. No data are given regarding the effects on the adrenals; and the effects of larger doses, which would probably increase sensitivity by causing involution of the cortex, were not ascertained.

In one group of animals bi-weekly tuberculin injections were commenced after 10 days of thyroxine treatment, so that by then any initial increase in cortical secretion would have been replaced by a decline. In those to which thyroxine was given after 28 days of tuberculin, any initial increase in sensitivity might have occurred between injections; or, as seems more likely, the repeated injections had acted as an alarming stimulus, with the result that the animals were in the resistance stage of the adaptation syndrome, and any such increase in cortical secretion was inhibited.

In the group of animals infected with B.C.G., 12 days' thyroxine increased sensitivity—an effect which can be explained in the same manner as above—but 14 days later it had decreased to half that of the controls. This may have been due to recovery of cortical function, so that the small amount of thyroxine still remaining in the body could now raise the level of secretion of the sugar hormones, and thus decrease sensitivity.

No comment whatever is made regarding the remarkable fact that in the animals which were being sensitised with tuberculin and given thyroxine, the cessation of the thyroxine was followed by the decline of the sensitivity to control level, but *not* below as in the B.C.G. group. Perhaps this discrepancy may be explained by the tuberculin-treated animals being in the resistance stage, so that the cortex did not respond to the stimulus of slight excess of thyroxine 14 days later. As B.C.G. is unlikely to have caused much general upset, and as these animals were only tuberculin-tested twice, there is no reason to suppose that they were in the resistance stage.

The finding that, in the B.C.G. group, cortisone or A.C.T.H.P. caused a well-marked decrease in sensitivity is no surprise, but the increase in sensitivity in the A.C.T.H.P.-treated group to three times, and in the cortisone-treated group to nine times, that of the controls 14 days later, is very remarkable. Though the authors suggest that hypersecretion by the thyroid may have been responsible, yet they do not appear to have examined the thyroid to find out if such was the case.

This phenomenon does not seem to be reasonably accounted for by the period of suppression of the production of endogenous A.C.T.H. which certainly followed the administration of these hormones, as this period surely could not have lasted for 14 days. This is conjecture, however, as there is no mention of the state of the adrenals in those animals. However, though B.C.G. is of low virulence in the guineapig, the effects of these powerful hormones in breaking down lymphoid tissue, or any fibrosis, plus the period of suppression of A.C.T.H. secretion which followed, and during which the non-specific resistance must have been low, may have had some effect on the infection. As there is no mention of the effects of B.C.G. infection on these animals, or the controls, this question must remain unanswered; but the fact that 3 days' administration of cortisone caused the sensitivity after 14 days to be three times that in those treated with one dose of A.C.T.H.P., would suggest that there may be some foundation for the above surmise. Unless no hormones were available, it is difficult to understand why their effects on sensitivity in those animals which had been sensitised by tuberculin were not ascertained, as the possible factor of the infection would thus be eliminated.

So far the criticism of this paper has been purely destructive, though the scanty data and inadequate investigation have necessitated much of it being hypothetical. It is therefore just and proper to suggest how the matter might be clarified.

The effect of smaller doses of thyroxine should be ascertained, as there are many contrary reports in the

Letters to the Editor

RESISTANCE TO P.A.S.

SIR,—Since 1947 we have treated more than 500 patients, with pulmonary and extrapulmonary tuberculosis, with *p*-aminosalicylic acid (P.A.S.). The results are most encouraging.[1]

In some cases, however, we have observed that the pulmonary lesions show regression for the first 4–5 months of P.A.S. treatment; then are stationary for some time; and later, about 6–8 months after the institution of P.A.S. therapy, progress again. Since January, 1949, we have routinely determined the sensitivity of tubercle bacilli to P.A.S. and streptomycin. (The determinations have been made at the State Bacteriological Laboratory by Dr. Brita Lagergren.) As is seen from the accompanying table, resistance to P.A.S. often appears after six months (the earliest being 112 days) of P.A.S. treatment. This has already been reported by others.[2] Combined treatment with streptomycin and P.A.S. is valuable both because of the additional therapeutic effect and the possible delay or prevention of resistance to streptomycin.[3]

* The treated patients received 12–18 g. P.A.S. daily, and most of them one or more short courses of streptomycin (1 g. daily for 15–20 days). The table includes 11 cultures regarded as resistant to streptomycin.

† Total of 171 cultures tested (from 148 patients).

‡ Expressed as maximal concentration of sodium salt of P.A.S. in Dubos fluid medium (mg. per 100 ml.), which permitted growth.

N.D. = not determined.

In the treatment of tuberculosis we use P.A.S. routinely, supplemented by short courses of streptomycin when serious complications are diagnosed or suspected, and as preparatory and preventive treatment before surgical procedures. The combination of P.A.S. with streptomycin in this way does not, according to our findings, prevent the emergence of resistance to P.A.S.

Thus it is important not to postpone necessary collapse treatment too long—i.e., *more than 4–5 months of* P.A.S. therapy is dangerous, since resistance to P.A.S. after that time is not uncommon (53% of the cultures from patients treated for more than 178 days were resistant to P.A.S.). The clinical course of the disease agrees in most instances with the sensitivity of the bacilli to P.A.S. This will later be reported in detail.

BRITISH SPAS AND HEALTH RESORTS

SIR,—A group of medical men interested in physical medicine, and particularly in the therapeutic powers of the British health resorts and spas, have held some preliminary meetings at 11, Chandos Street, W.1, for the purpose of discussing the methods of study and development of these resorts. It was decided not to revive the pre-war British Health Resorts Association, but to create a new organism—an association including medical and non-medical men interested in this question. As hon. secretary of these meetings I was entrusted with the task of ascertaining the views on this subject of the British medical profession, and I should be grateful to receive any comments on this plan for the development of our spas and health resorts.

Great Britain possesses some of the finest spas and health resorts of the world, and it is, in fact, in this country that modern climatotherapy originated. The renewal of interest in the methods of physical medicine, the difficulties of travel abroad, and the desire to bring into this country many overseas visitors are sufficient factors to stimulate us to more *definite action for the* development of these outstanding physical therapeutic agents.

7, Wimpole Street, London, W.1.

A. P. CAWADIAS.

THE REGISTRAR'S FUTURE

SIR,—For some time the position of senior registrars vis-à-vis consultant posts has been causing many of us grave anxiety. If the position in England is similar to that shown by recently published figures for Scotland, the number of vacancies for consultants in the National Health Service during the next few years is likely to be very substantially less than the number of senior registrars completing their training. Not only is the number of registrars now in training larger than is necessary to provide for the filling of vacancies due to retirement and casualty, but also consultants have had their retiring-age extended to 65 under the Act, while newly appointed ones are a relatively young group; so retirements in the next 10 years will be fewer than in subsequent years.

Steps are in contemplation to reduce registrar establishments to provide numbers of fully trained specialists not greatly in excess of requirements; otherwise there will be many young men fully trained as specialists who, in their middle thirties, must try to find some other form of medical employment. But these steps will be too late to help many who are now in the senior-registrar grade.

There exists a serious shortage of specialists of many sorts in the medical services of the Fighting Forces, the Colonial Medical Service, the Sudan Medical Service, &c. There are, moreover, vacancies for professors, readers, and teachers in the medical faculties not only of Colonial universities and university colleges, but in Egypt, Iraq, and similar Middle East countries where it is urgent that the tradition of British medical teaching should be maintained. The Services offer not only interesting work for which many of the senior registrars now completing their appointments are particularly well fitted, but also a career.

The university posts are comparable with those in teaching hospitals in this country, with the addit conjoined ureters face the small opening in the bowel mucosa. Two or three fine silk sutures fix the ureteric loop in position.

[2] Delaude, A., Karlson, A. G., Carr, D. T., Pfuetze, K. H. *Proc. Mayo Clin.* 1949, 24, 341. Widstrom, G., Swedberg, B. *Nord. Med.* 1948, 40, 2225.

[3] Graessle, O., Pietrowski, J. *J. Bact.* 1949, 57, 459. Karlson, A. G., Pfuetze, K. H., Carr, D. T., Feldman, W. H., Hinshaw, H. C. *Proc. Mayo Clin.* 1949, 24, 85.

The seromuscular edges at each end of the gutter are now picked up and held in apposition by two Babcock's forceps. A little tension on these forceps facilitates the closure of the seromuscular incision and the burying of the ureteric loop by two continuous sutures of fine silk. About 2 in. of the ureteric loop is buried. The incision in the posterior peritoneum is closed so that the anastomosis is almost extraperitoneal, and the wound is closed with a fine drainage tube down to the ureterocolostomy.

The advantages of this technique over the Coffey and similar techniques may be summarised as follows. There is only one site to plan on the colon for the proposed anastomosis, whereas with a short sigmoid the placing of two may be awkward. Moreover, the optimum site can be quickly judged from the position of the junction of the two ureters when the loop is made to lie parallel with the adjacent segment of sigmoid. There is only one opening made in the colon, and the technique does not involve the additional procedure of threading the ureter into its lumen. These points contribute to a more simple operation and a much shorter operating-time.

The loop transplantation also gives an excellent functional result with immediate drainage. It is noticeable that sometimes drainage is delayed in the Coffey II transplantation, presumably because of some slight temporary obstruction. I have always held that ascending infection is more likely if the ureter is drawn into the lumen of the bowel. A small hole in the mucosa at least simulates a ureteric orifice, and would seem to be more likely to prevent intimate contact with the fæcal contents even if an actual valvular effect cannot be attained. Coffey probably had this in mind when he devised his no. III technique. Also it is possible that the combined efflux of urine at the one orifice may be a further safeguard against infection.

Chigwell, Essex.   D. LANG STEVENSON.

COST OF MEDICAL REGISTRATION

SIR,—I shared Viscount Addison's belief[1] that it cost five guineas to register. I tried it last week; I received five shillings change.

King's College Hospital,
London, S.E.5.   DAVID ADDERLEY.

SOME LIMITATIONS OF PSYCHIATRY

SIR,—I enjoyed reading Dr. Haldane's thoughtful article in your last issue. Whether psychiatrists will agree with him or not, the physician who interests himself in neuropsychiatric illness will appreciate only too well what Dr. Haldane means when he says that the psychoneurosis is only one manifestation—one outward expression—of the patient's personality.

Where, however, I differ from Dr. Haldane is in his conclusion, as I understand it, that superficial therapy —what he calls a " psychiatric placebo "—is not really worth while, because it is not likely to effect any very fundamental change in a psychoneurotic patient. His conclusion that " the symptoms of a psychoneurosis are themselves of minor import relative to the underlying disorder " has not engendered in me the feelings of therapeutic impotence that make him end his paper with the words " we must also be still more realistic and realise that at present, apart from a little palliation, many cannot be treated at all."

On the contrary, this conclusion has stimulated me in the past to concentrate more than ever on attempting to relieve the symptoms of, for example, an hysteric, rather than on trying to change the rigid attitude of mind which I have no doubt he possesses. Often all that is needed for the patient to return to a useful job of work is relief from his symptoms, and I am convinced that these people will often remain surprisingly free from the relapses which are sometimes too freely ascribed to them.

In spite of my disagreements, I should like to congratulate Dr. Haldane on his courageous challenge to physicians and surgeons. We must ask ourselves what exactly we want from the psychiatrists to whom we refer patients, and—perhaps more important—how we expect these patients to benefit from such reference. The time has indeed come when psychiatrists should protest against the tendency to use their departments as therapeutic dustbins.

Ashford Hospital,
Ashford, Middlesex.   A. BARHAM CARTER.

FAMILIAL GLOMERULONEPHRITIS

SIR,—The recurrence of glomerulonephritis in several members of a family must arouse suspicions of the presence either of some inherited intrinsic renal weakness or alternatively of a common extrinsic factor. Certainly the presence of the condition in successive generations, together with other undoubted congenital abnormalities, as described by Dr. Hawkins last week, leaves little doubt about the hereditary origin of some cases. However, instances do occur from time to time in which the presence of a common infecting organism would appear to be the most important factor in ætiology.

In May, 1946, I had under my care at St. George-in-the-East Hospital 3 members of a family of 8. These 3, who belonged to the same generation, were suffering from acute diffuse glomerulonephritis, Ellis type I. The family, consisting of mother, father, 4 children, and 2 grandchildren, all living together, had shortly before coming under observation been treated at a nearby municipal clinic for suspected scabies. When seen by me, 2 of the affected members of the family and the 2 grandchildren had typical impetiginous skin lesions from which hæmolytic streptococci were grown. The same organism was obtained from the throat of the 3rd affected member. No congenital abnormalities were present in any of the family, nor was there any history of allergic illnesses.

West Middlesex Hospital, Isleworth.   R. TEPPER.

THE MENTALLY HANDICAPPED CHILD

SIR,—I have read with great interest the article of another mother on this theme. When my boy was born he had the cord tight around his neck. He was asphyxiated, and it took 15 minutes to revive him and make him cry. When he " did not do the things which a normal baby did at his age " I knew that he had suffered a brain injury.

At 2 years the boy learned to walk and to talk, and at 3 years had a good vocabulary and liked to make conversation, but was completely unable to use his hands for any purposeful activity, and showed no interest in playing or in doing anything for himself. At 5 he learnt to feed himself with a spoon and also started to dress himself, but it took 3 more years before he could be induced to try buttoning-up things. His disability became more obvious as time went on, whereas his speech, apart from a certain abruptness, developed quite normally. He was 9 when he came to England, and quickly learned to speak English without forgetting his German. He also learned, in a few months, *to read English; but he* was never able to write, or to draw even a simple geometrical figure, and he remained unable to imitate movements or to do anything with his hands, no matter how often one showed *it to him.* Apart from a few simple movements, which he learned by having his hand guided over and over again, he was almost helpless. But he was not paralysed, and his arms and hands were well formed and well developed.

Besides his physical disability he showed strange mental limitations. He could not solve a simple form-board test, and was unable to build with bricks or to accomplish even the most simple constructional task. Labelled as " doubly literature regarding the effects of hyperthyroidism on human and animal tuberculosis.[5, 6] It is an old clinical observation that hyperthyroidism seems to have an inhibitory influence on tuberculosis, and that hyperthyroidism has many features in common with adrenal insufficiency. It has recently been shown[5] that 30 μg. of thyroxine bi-weekly (one tenth of the dosage of Long and Miles) produces an increase, and thyroidectomy a decrease, in the survival-time of the guineapig with tuberculosis. The effects of thyroidectomy or larger doses of thiouracil would therefore be of interest, as it is likely that sensitivity would be increased.

---

[1] See *Lancet*, April 29, p. 825.

It might be possible to determine whether the cortex had been exhausted or not, as a result of excess thyroxine, by the administration of a minimal dose of A.C.T.H. and the observation of its effects on sensitivity. A large dose might mask the exhaustion unless it was absolute, which seems unlikely. The dosage administered by Long and Miles was, according to the data, 600 times that which would give unequivocal evidence of adrenal stimulation in the test rat.

The old theory that the thyroid and the adrenal are in opposition is not in accord with recent evidence,[7] which is more in favour of a partnership between these glands in the metabolic processes, except when the balance is grossly disturbed, as in hyperthyroidism. The hypertrophy of the cortex followed by exhaustion produced by thyroxine, and the involution following thiouracil or thyroidectomy, would seem most readily explained by the concept of increased tissue utilisation of hormones.[8] Thus, excess thyroxine, by increasing the rate of metabolism, increases the utilisation of the sugar hormones, and brings about their increased secretion to meet the demand, while the lack of thyroxine brings about decreased need for these hormones and involution of the cortex. This theory seems most logical, as there can be no doubt that it is for the purpose of supplying hormones to the tissues that the endocrine glands exist at all. The influence of the target tissues cannot therefore be ignored, as is so commonly done.

The report by Long and Miles can no more be regarded as indicative of any influence of the thyroid on hypersensitivity than this analysis can be taken as ruling out the possibility.

Edinburgh. H. MORROW BROWN.

PREGNANCY AND PULMONARY TUBERCULOSIS

SIR,—Dr. Stewart and Dr. Simmonds mentioned in their letter last week the importance of X-ray observation of pregnant women.

Jacobs,[9] at Paddington Hospital, was one of the first in this country to undertake a screen examination of the chest of all women attending an antenatal department. From January, 1943, to April, 1946, a total of 4430 women were screened. He found 27 cases (0·61%) of active pulmonary tuberculosis requiring immediate admission. There were 11 cases (0·25%) possibly active, and 30 (0·67%) probably inactive. Thus the total cases of tuberculosis were 68 (1·53%).

From January, 1946, to August, 1949, at University College Hospital 3581 expectant mothers had an X-ray examination of the chest. Among these pulmonary tuberculosis was discovered in 28 cases (0·74%)—13 active and 15 inactive. All these women had had the usual chest examination by a medical officer in the antenatal clinic. In only one were any abnormal signs discovered by ordinary physical examination.

Since routine chest radiography is being made available for large groups of the population, we would plead that priority be given to expectant mothers. Dr. Turner, in his article of April 15, has shown that one of the "danger periods" is during the first four months of pregnancy. It is the practice in this hospital for every expectant mother to have a chest X-ray examination as soon after her first visit as possible. If the mechanists have their way, then every primigravida will have a radiological examination of her pelvis. We feel there is just as strong a case for routine X-ray examination of the chest.

In view of the discussion in the medical and lay press on the allocation of beds for tuberculosis, we should like to point out that at this hospital a number of antenatal beds are reserved for tuberculous mothers.

MITCHELL-NELSON TEXTBOOK OF PEDIATRICS

SIR,—Your review of the excellent Mitchell and Nelson *Textbook of Pediatrics* (April 22, p. 766) is hardly fair in its criticism of the book. You say: "It is a little startling to find emotional growth and development discussed in less than a page." There is a 14-page section entitled Mental and Emotional Development, quite apart from the chapter on Psychological Disorders, in which mental and emotional development are inevitably discussed. I agree that the sections on emotional development and behaviour problems are inadequte, as in other textbooks of pædiatrics, but your statement is misleading.

R. S. ILLINGWORTH
Professor of Child Health.

⁂ Our comment was perhaps too emphatic. Though the passages headed *Emotional* Development occupy less than a page, a good deal is said on this subject in the rest of this section and in other parts of the book.—ED. L.

LOOP TRANSPLANTATION OF URETERS

SIR,—I have been using a modified technique for transplantation of the ureters into the colon which has certain outstanding advantages over the more commonly practised methods. A brief account of it may be of interest, since I am not aware that it has been described before.

The abdomen is opened through a left paramedian incision and the bowels are packed off. Separate incisions are made through the posterior peritoneum over each ureter, and both are mobilised up to the bladder. Each ureter is divided just above a long curved clamp such as Moynihan's gallbladder forceps, and the distal stumps are ligatured. No traumatising instrument is placed on the proximal ends, which are each wrapped in a swab. A fine silk suture is inserted through the end of the right ureter, and the silk is left long. With the left index finger as a guide, a long curved artery forceps is gently tunnelled through behind the mesosigmoid from the left incision in the posterior peritoneum to the right. The silk attached to the right ureter is picked up and drawn through to the left side of the mesosigmoid with the right ureter. The end of each ureter is cut obliquely, and the pointed extremities are then conjoined by two fine silk sutures.

A ureteric loop has now been formed by the left ureter passing downwards and inwards and the right ureter curving upwards and outwards. The ureteric loop is laid alongside the sigmoid colon so that it lies in the position of maximum ease. With the proposed anastomosis in view, a little adjustment enables the optimum site to be marked by two stay sutures on either side of the bowel wall. The segment of the colon is picked up by four Babcock's forceps to facilitate making a longitudinal incision about $1^3/_4$ in. long through the seromuscular coats of the bowel over one of the tæniæ. A very small opening is made in the protruding mucosa at the level of the marking sutures, which should also be the mid-point of the incision. The loop is now placed in the gutter thus formed so that the oblique openings of the

resting place was the steps themselves in full view of the passers by and exposed to the inclemency of the weather. Even now in my dreams, I can see that patient, plodding stream dragging their arthritic limbs up that staircase."[1]

At the present time, as Dr. Collings remarks: "The conduct of . . . the individual practitioner is inextricably interwoven with commercial and emotional considerations. . . ." How can it be otherwise? Unless the doctor is the fortunate possessor of private means, he is nowadays forced to be a head-hunter in order to live, pay his way, and maintain his wife and family. In days gone by, his income was largely composed of fees from private practice. Now, out of 48,059,201 people in this country, 45,816,426 (95·3%) have joined the National Health Service; and private practice, as a source of income, has practically ceased to exist. In Middlesex, once a fruitful source of private fees, 97% of the population are on doctors' lists; in Sussex, 91·8%; and in Surrey, 93%. To meet his commitments the practitioner needs a minimum of 2250 on his list at the present rate of remuneration; and any doctor who has that number is likely to be required to supply, on average, 45 items of service per day—slightly less in the summer, and slightly more in the winter. If he has children to bring up, he will require more money and must therefore collect more heads and get through more work.

Dr. Collings gives a devastating picture of the practitioner's workshop: "Few skilled craftsmen, be they plumbers, butchers, or motor mechanics, would be prepared to work under conditions or with equipment as bad (comparably) as that tolerated by many doctors working in industrial practices." That this is true there is no doubt, but is it always the doctor's fault? Certainly he is to blame for dirt and untidiness; but how many doctors in industrial areas can afford £1000 or so to have the place they would like? The answer is obvious: the doctor's workshop of the future must be provided by the State. Then and then only shall we be able to relegate to the museum those blots on our civilisation described by Dr. Collings, and seen by me in many parts of England.

Reviewing the administrative machinery of the National Health Service, Dr. Collings rightly describes the policy as one "of fragmentation, not integration." For instance, the responsibility for care of an expectant mother may be shared by regional hospital board, local health authority, and local executive council, before she settles down at home with her baby; and there is no direct liaison between these bodies. No wonder the machinery is creaking badly.

There is also good foundation for Dr. Collings's observation that executive councils are preoccupied with day-to-day routine work to the exclusion of planning. He attributes this to the attitude of the permanent staff, inherited from the old National Health Insurance days—what one may call "the panel mind." Can anyone in fact tell me of an executive council who have had on their agenda a debate on health centres? A local medical committee in full session will spend much of an afternoon debating such items as "is glucose a food or a drug?" when they would be better employed in considering policy for the future, leaving routine work to a small subcommittee.

What of the remedies? If able men are to be attracted to general practice they must be assured: (1) of a living wage on qualification with prospects of making a good income by the age of 40 or under; and (2) of being able to reractise their craft without having to build up a rather [illegible] connection. Remuneration should, I submit, mind whrounded as follows:

that is neeclly an expenses allowance sufficient to meet all of work is repenses (after the system of some of the public services where marriage allowance, rent, rates, fuel, light, servant, upkeep of motor-car, &c., are granted).

2. Increment for length of service up to 50 years of age.
3. Administrative, specialist, or extra-duty pay if such work is performed.
4. Locality allowance for specially difficult areas.
5. A small capitation fee as a reward for responsibility accepted, up to 2500 patients.
6. Mileage allowance as at present.

The able man would then know where he was; he would know the prospect in front of him; and he would have time to use his clinical skill free from financial anxiety. The only alternative to this method is a full-time salaried service.

It is quite obvious that some form of health centre or group practice must be provided without delay. What the practitioner needs, in order to provide a better service, is: (1) more time per patient, which would be obtainable through clerical assistance; and (2) free and rapid access to a laboratory and X-ray department. Each health centre should meet these basic requirements. The size and equipment of a centre would, of course, depend on the locality. Outlying villages might be served by a mobile centre, consisting of a large motor-van, staffed by a doctor and nurse-dispenser. Villagers have told me that such centres would be a boon to the countryside.

Finally I would suggest that one method by which integration and an improved standard might be achieved is by setting up the Central Medical Board proposed in the Coalition Government's white-paper.[2] It was a great misfortune that the idea of this board was dropped; but it did not find favour with those who believe in fragmentation rather than integration.

The board would take the place of the present Medical Practices Committee and work in close liaison with the Central Health Services Council. It would differ from the latter inasmuch as its function would be executive, not advisory; and it would see to the satisfactory day-to-day working of the medical-practitioner service. I submit that the replacement of the Medical Practices Committee by such a board is necessary in order to obtain, not only a central controlling agency, but also an employment agency and medical pool, from which casualties would be replaced as required; a posting agency for young men wishing to join the service; and a supplying agency for those authorities finding themselves short of medical personnel. It could also be used as a transfer agency for those who, for health or other reasons, wish a change of district.

In conjunction with the Central Health Services Council, the board could define the future province and function of general practice. As Dr. Collings says, so long as this is undefined, the general practitioner is in no position to defend himself against those who would debase him.

Worthing. HAROLD LEESON.

SIR,—I am becoming rather tired of reading letters in THE LANCET from doctors in general practice who wonder why no-one is going into practice. The reason is that it is practically impossible to get established in practice unless one has a large amount of capital, which nowadays cannot be borrowed.

I, like many others, am training to be a specialist in a small branch of medicine. I am doing this, not with any great confidence that I will become a specialist when my training is over in a few years' time, but because it is the only way I can find employment. I do not particularly want to be a specialist in any case, but I cannot get into general practice except as an assistant.

I have investigated carefully the methods of entry into practice. I can obtain a post as assistant to a practitioner with a large list, but beyond this the future

---

H. Experiences of a Locum. Private circulation.

[2] See Leeson, H. H. Your Doctor of the Future. High Wycombe, 1944.

handicapped" he was declared "ineducable" by the authorities, and we sent him to a private school for "children in need of special care." There he became worse after a time. The principal of the school prophesied that he would deteriorate, and that he was "unlikely to live to his 20th birthday." Michael was then 15. I gave up my job as a medical officer and took the boy home, to devote all my time to his care, and to the study of his disability.

I studied brain anatomy, pathology, and physiology, conditioned reflexes, behaviour-embryology, and experimental psychology; and out of these studies a picture of the "human mind" emerged, very different from the accepted one.

First, I came to realise that what we measure in our so-called "intelligence tests" are sensory-motor performances, depending on an intact nervous system. A lesion anywhere between sensory receptor and motor effector renders these tests valueless, because the faulty or absent response to a stimulus is due to a break in the pathway of one or more sensory-motor systems. It is not the result of an "intelligence" defect, whatever that may be.

To be unable to imitate seen movement is not due to a "mental" defect, but a visual one, or better, to a defect resulting from destruction of the midbrain ganglion in which visual fibres are integrated with kinæsthetic fibres and where visual impressions are used for motor reactions. If these ganglia (the superior corpora quadrigemina) are severely injured, the ability to imitate seen movement is greatly diminished. If they are completely destroyed, imitation of movement becomes virtually impossible. In addition, destruction of these ganglia abolishes all visual reflexes, prevents the spontaneous understanding of form and space (which concepts are both based on visuokinæsthetic integrations), and deprives the child of one of the most important incentives for learning—the curiosity to find out how things are done. It tends to make large parts of human activity incomprehensible to the child.

If this handicap is recognised in time and dealt with, the child's difficulties can be overcome. All blind children suffer from the same mental handicap in an even more severe form. By taking it into account, and adjusting our teaching methods accordingly, we are able to develop their mental faculties. Nobody would expect a blind child to imitate seen movement or recognise seen shape or understand visual space or the visual aspect of human activity. Children with a visuomotor defect are educationally very much in the same position in spite of their ability to see.

When I had recognised that to teach Michael meant regarding him almost as if he was blind, he was already 19 years old. Tuition at this age, and after so many years of wrong approach is not easy; nevertheless he learned to write within 2 months, and is now slowly learning all the movements necessary for everyday life. With growing independence and understanding of space relations his "mind" is fast developing. How far he will be able to advance, being already 20, remains to be seen. But I am absolutely sure that no "intelligence" defect would ever have developed in him if 19 years ago I had known what I know today.

At the moment I am working with mentally handicapped children and am trying to put some of my educational ideas into practice through the Association of Parents of Backward Children. My observations have strengthened my belief that many mental defects are the result of unrecognised birth hæmorrhages affecting tributaries of the vein of Galen, and injuring ganglia of the mesencephalon or telencephalon. But the more children I see, the more I realise the immensity of the task and of the urgent need for intensive and unprejudiced research into the causation and educational treatment of mental handicap. Methods of investigating the brain and its reactions are rapidly advancing, and there is no justification anymore for the fatalistic attitude of: *Ignoramus et semper ignorabimus.*

London, W.1. LISE GELLNER.

GENERAL PRACTICE TODAY

SIR,—Only recently have I had time to complete my study of the Collings report and to read the voluminous correspondence that has grown up around it.

It is not for me to say to what extent Dr. Collings's strictures on general practice are in accordance with the facts. I venture to suggest, however, that to the extent that they are, both Dr. Collings himself and all your correspondents have to a large extent missed the point as to their cause and cure.

Dr. Collings writes:

> "While other branches of medicine have progressed and developed, general practice, instead of developing concurrently, has adapted itself to the changing patterns; and sometimes this adaptation has in fact been regression"

And again:

> "Through the agency of the regional hospital boards decisions of policy and principle relating to hospital and specialist services are being taken. No similar decisions are being taken on general practice."

Surely this is fundamental. Both before and after July, 1948, the specialist has been working with his colleagues to provide an organised service in hospital, whereas the general practitioner has worked in isolation and, except where a partnership exists, in competition with his fellows.

It is true that during the negotiations that preceded the National Health Service Act the G.P.s came together to oppose it. They were also concerned, quite rightly, with their remuneration under the scheme, but gave little thought to their rightful place in it or to opportunities for doing good work under it. They only asked to be left alone, and they have got what they asked.

I have always looked on G.P.s as the shock-troops of medicine—the most essential link in the health chain. However far specialisation may develop, the individual who first sees the patient, makes a diagnosis, and, if necessary, selects the specialist, must always take first place. But, for efficient service, the G.P. cannot work alone and in competition with his fellows. He must be part of an organised team for the prevention and cure of disease. Moreover, *the struggle for patients*, inevitable under a capitation system, renders true coöperation impossible. A full-time salaried service of G.P.s as an integrated part of the health service is therefore essential. This is the lesson of the Collings report as I see it.

House of Commons, London. SOMERVILLE HASTINGS.

SIR,—For five years my travels took me all over England as a G.P. From this and further experience as an examining medical officer I can assure you that the picture presented by Dr. Collings is, if anything, underpainted. One experience still haunts me:

> "The Consulting Room was on the first floor of the house, unkempt and untidy, the Doctor's desk was littered with papers of all sorts, periodicals, cuttings, advertisements from a local bookmaker, National Health forms and certificates. The drawers contained books, catalogues, patients' records, cigarettes in profusion, broken instruments, flotsam and jetsam of *all sorts, all mixed up together.* One corner was screened off to form a sort of dispensary, and here the conditions were even worse. . . . The shelves *looked* as if they had not been dusted for years and contained a heterogeneous collection of drugs, dressings, packets of cigarettes and instruments all jumbled up together. . . . Wool in open packets, dressings and bandages contended for pride of place in this motley array. A *large* tin can provided the water to fill the medicine bottles. The Waiting Room even worse. This led out of the Consulting Room ar bare, cold and depressing with about 20 chairs an ough . . . Entrance from outside was gained by a flight tæniæ. steps of the ladder pattern leading from the cosa at the ground. Thus not only had the sick ar o be the negotiate the staircase the best way they co laced in Waiting Room was full, as it often was ngs of the

centres. Teaching hospitals are usually situated in areas where there is a shortage of doctors, and the construction of such centres would relieve the pressure on the practitioners of the area. EX-STUDENT.

SIR,—Although, as a newly qualified doctor, I lack all first-hand experience of general practice, I feel I may legitimately join in the controversy aroused by the Collings report. I write from the viewpoint of one who agrees that the aim of medicine should be to keep the patient out of hospital as far as possible, and who hopes that the general practitioner may be allowed to play his full part in achieving this aim. I further believe that, in both medical and human interest, general practice, has, ideally, great advantages over other forms of practice; for in no other field can disease and sick people be studied through long periods of time and in their social context.

However, when considering a career in this field of medicine, one is faced with an impressive and depressing array of evidence of the widespread loss of professional standards and opportunities suffered in general practice, in the form of the doctors' letters brought to hospital outpatients, the warnings of one's seniors, and now the Collings report. The effect of this evidence on my contemporaries is that general practice has fallen into such disrepute that it is the career of choice of far fewer than will, presumably, be engaged in it.

The most indignant critics of the Collings report cannot deny that this situation is critical. A branch of medicine, the fundamental importance of which you, Sir, have repeatedly stressed, is threatened with extinction. To save it action is required on many fronts, of which I would suggest the following:

1. The quality of the general-practitioner service in the future will depend on the training and morale of the practitioners entering it. At present, medical education fails to give a balanced view of the rôle of medicine. Taught entirely in well-equipped hospitals where patients, isolated from their homes and jobs, are analysed in fine detail, medical students are but distantly aware of the scope of general practice, and young doctors enter it ignorant of its problems and unprepared for the effort required to maintain professional standards. Closer contact with general practice for students, in the form of lectures and some practical participation, would enable young doctors to make more balanced judgments, and would ensure an attitude of more constructive criticism among future recruits to practice. This is a question with which medical schools and the British Medical Students' Association should surely be concerned.

2. As Collings suggests, it is time that the profession reached a clearer definition of the scope and function of general practice. There is already a tendency to accept low standards as inevitable, and for hospitals to hold, and general practitioners to accept, a view of practice which reduces its functions to that of a medical sorting office. The work of good general practitioners is sufficient answer to this attitude, but the tendency to further limit the professional opportunities and facilities of general practice, which has been aggravated by the N.H.S., must be reversed, and the professional organisations should devote some of their zeal and leadership to this end.

3. As Collings brought out, at the root of much of the dissatisfaction, frustration, and inefficiency of general practice lies the question of working conditions. Part of the remedy for this lies in our own hands, in the formation of group practices, and I feel sure that among younger doctors at least there will be no lack of enthusiasm for this idea. But it is also a job for the Government; for without the provision of properly equipped medical centres of some description, no doctor who wishes to do good medicine will enter willingly a working-class practice. The conditions in the worst industrial practices, as described by Collings, would break all but the most ardent crusading spirit.

Are we to accept without strong protest the cuts in expenditure which prevent any of the promised health centres being built?

University College Hospital,
London, W.C.1. ANTHONY RYLE.

Obituary

ARTHUR BEENY APPLETON

M.A., M.D. CAMB.

Professor Appleton died on April 22 at St. Thomas's Hospital, where he held the chair of anatomy from 1934 to 1948. In the latter year he joined the staff of the new Institute of Animal Physiology which is being set up by the Agricultural Research Council. In preparation for this new work he had lately visited veterinary schools in the United States. But illness interrupted the study of the surgical anatomy of farm animals which he had already begun at the Zoological Society and on which he planned to publish a comprehensive treatise.

He was educated at the City of London School, at Downing College, Cambridge, and at St. Bartholomew's Hospital. He qualified in 1914 and almost at once joined the R.A.M.C. in which he served for the next five years. On demobilisation he held the post of medical supervisor of Ministry of Pensions orthopædic clinics in the Cambridge area, before becoming senior demonstrator in anatomy in the University of Cambridge. In 1922 he was awarded the Horton Smith prize for his M.D. thesis; in the following year he received the Symington prize for anatomical research; and in 1926 he became lecturer. Four years later he was elected a fellow of Downing College.

To these years belong his research on the muscle and nerves of the tetrapoda and on bone growth. Later, after his appointment to the chair at St. Thomas's, he investigated the development of the lung, and he was at work on his manuscripts on this subject shortly before his death. He was a member of the editorial board of the *Acta Anatomica*, and he had himself written a *Guide to Vertebrate Dissection for Students* (1929), besides collaborating with W. J. Hamilton and I. C. C. Tshaperoff in *Surface and Radiological Anatomy* (1938). His students will remember his beautiful blackboard drawing, and the talent he showed as an artist was happily linked with his other work by his appointment as professor of anatomy at the Royal Academy of Arts. His interest in posture and the locomotor apparatus was reflected by his service to the Chelsea School of Physical Education; on whose governing body he represented the University of London. He had examined for the Universities of London, Liverpool, Manchester, Cardiff, and Cambridge.

F. G. writes: "Professor Appleton will be most vividly remembered for the work which he did in London at St. Thomas's Hospital Medical School, and during the years 1948 and 1949 as president of the Anatomical Society. As secretary of the society I worked in close association with him during these two years; his great friendliness, his wide knowledge of anatomical matters, coupled with an essential modesty, made this association an experience I shall always remember with gratitude.

"It is fitting, however, that some tribute should be paid to an earlier phase of his career. I entered the old Anatomy School at Cambridge in 1920, and very soon came under his influence as a teacher. There must be many from that period who remember his enthusiasm and freshness of outlook, for, equipped with a most impressive knowledge of detailed human anatomy, he was one of the first to apply experimental methods in research in a British department of anatomy. At this time he was coöperating actively with Prof. J. T. Wilson in the establishment of the courses in anatomy for the natural sciences tripos, taking himself a large part in the teaching of vertebrate morphology. His own main interest then was in the problems of comparative myology, and here his most important influence was felt in his application to the classical morphology of an outlook which was essentially experimental and functional. It was in this enthusiastic encouragement of modern methods and their application on an unusually wide basis of detailed descriptive knowledge that the chief characteristic of his work lay. In him we have lost a fine anatomist and a valued friend, whose influence on the development of the science he had so much at heart was greater than perhaps he himself realised."

Professor Appleton married in 1918 Eva Gertrude Plewman, who survives him with a son and a daughter. He was 61 years of age.

is very uncertain and the chances of becoming a partner are small. This enables the principal to maintain a large list and have his work done cheaply by a doctor who is paid a small salary. In fact the principal can even claim income-tax rebate by employing me. I can be sacked at a month's notice if I am not prepared to work 12 hours a day.

A situation of under-employment is developing in the National Health Service at a time when more doctors than ever before are needed. This is not the fault of the service; it is due to the medical profession's main interest being money. In the end it will lead to a full-time salaried service; and the sooner this appears the better, for the present situation cannot continue indefinitely.

I do feel, however, that medical students should realise that their chances of establishing themselves are very small under the present system. I believe that many would seriously consider changing their profession while there was still time if they knew the true facts. There has been little publicity to expose the exploitation of young doctors that is now going on.

REGISTRAR.

SIR,—I qualified only recently, but I should like to discuss the problem in relation to my education, so recently concluded.

The teaching hospitals, and hospitals generally, could do a great deal to improve the situation. In the teaching hospitals the patients offered for study are highly selected; the rare and more complicated cases are encountered, and they are taught on by specialists. The standard bedside inquisition of the student passes from history to examination and from there to as many possible laboratory investigations as he cares or manages to think of in the space of sixty seconds. At the end of all this he is asked for his diagnosis, which, if he has his wits about him and possesses good eyesight, he proceeds to read from the bed-ticket. Usually no attempt is made to elicit the logical steps by which the diagnosis could have been reached, and there is no desire to limit the investigations to such as will finally settle the matter. The great man is often a very bad offender in this respect himself, and will not see the patient until all investigations, including the blood-rhubarb, have been completed. Yet after a short interval the student may become a general practitioner and will be expected to diagnose without any ancillary investigations.

There is no reason why the cases should be selected in this way. Within four miles of the institution where I have been trained there are several general hospitals which between them have ten times as many beds as there are in the teaching hospital. The patients are attended by consultants as well qualified as those in the teaching hospital; often these consultants have trained in the teaching hospital and have taught there when they were registrars; yet no attempt is made to use their patients as material for teaching, though the material is less selected and thus more suitable for instructing future general practitioners. My university is not the only one, I believe, which wastes clinical material in this way.

Not only is the material in the teaching hospital selected, but it undergoes further selection as to which cases will actually be used for teaching. Very often it is the rare case that is used; and here the registrars are worse offenders than their chiefs. I have been treated to a two-hour discourse on differentiation between various types of congenital heart-disease; I have had a half-hour talk on the treatment of multiple myelomatosis; yet no-one has told me how I can make an old lady with lobar pneumonia comfortable—in fact I have not seen a case of lobar pneumonia in the hospital.

Similarly in the final examination, in the viva I was asked about voice changes in myxœdema, and cases of pulmonary actinomycosis and rare muscular dystrophy were on show. Thus concentrating on the esoteric, the student does not graduate looking forward to helping his sick friends, who are suffering from ordinary diseases, in general practice; instead he dreams of the day when in an immaculate pin-stripe suit, and attended by a large retinue of registrars and students, he will talk learnedly about the Smith-Schmidt syndrome, two cases of which he has seen in the last thirty years. Generations of students are now growing up whose dearest wish, partly as a result of their education, is to avoid going into general practice; those with the intellect, the push, and the family connections will have their way, leaving their less fortunate brethren to labour in the outer darkness.

Dr. Collings mentions that the standard of pædiatric work and psychiatry is low in general practice. The teaching I have received in these subjects certainly does not fit me to look after children or nervous disorders. Often the task of a student in search of knowledge is complicated by house-surgeons, members of the nursing staff, and porters, who are detailed to guard the door of the sanctum. There are still consultants on the staffs of teaching hospitals who refuse to teach.

With all its shortcomings, the hospital still offers the best training-ground for doctors; but this too will become soon the province of the trainee specialist. A friend of mine, a registrar in a general hospital, once remarked in conversation that he had no intention of working for a higher qualification and that he wanted to go into general practice after he had gained more experience. Hearing of this, a consultant who had recently joined the hospital suggested to him that, if he was not working for an examination, he might leave and make room for someone who was.

Besides fulfilling the tasks already allotted to them, the hospitals and the teaching institutions could help the general practitioner in other ways. Prof. R. Platt mentioned in a recent article in the *Practitioner* how the diagnosis of a case could have been clinched quite simply by taking a proper history and doing a blood-count; instead the general practitioner gave the patient a bottle and reassured her in such a way that she became a neurotic and an invalid. The doctor could have done the blood-count himself, as some rare practitioners do; but this is not possible for one who sees thirty patients in two hours. The teaching hospital would not have been satisfied to do the blood-count and send the report to him for the next day: they would have treated the good lady, given her enough medicine for a week, and told her to go to the doctor when it was finished; and about a fortnight later the doctor would have received a letter advising him what to do. At present there seems no way in which the general practitioner—in an industrial practice anyway—can get access to laboratory facilities which would put his work on a scientific basis. Such pathological services could easily be provided by hospitals, but until that is done one can hardly blame the young doctor when he only gives as good a service as old X.Y. down the road, who qualified at the Back-of-Beyond University in 1905 and has not read a medical journal or book since.

Dr. Collings suggests that the establishment of health centres would improve conditions. In preparation for this, would it not be a good thing to build one or two such centres and attach them to teaching hospitals? Several ends would be served. Postgraduates wanting to train for general practice could do so under ideal circumstances; such centres would offer better standards of comparison for the local general practitioners than old X.Y.; and the various problems of staffing, organisation, equipment, and design could be studied at leisure in readiness for the day when economic circumstances will be favourable to large-scale building of health

Notes and News

REMUNERATION OF GENERAL PRACTITIONERS

The Minister of Health is proposing to make a further inquiry into the professional incomes and expenses of general practitioners, on the basis of information provided by executive councils and the Inland Revenue authorities. At a meeting on April 3 with representatives of the General Medical Services Committee, the Minister stated that the Government's "wage-freeze" policy could not be disregarded, and he was not prepared to make any increase in the central pool on the facts before him. The inquiry into payments would relate to earnings in the year ended March 31, 1950; this information would be obtained from executive councils. Secondly, in order to discover what the practice expenses had proved to be in the National Health Service, the Inland Revenue authorities would be asked (if the profession agreed) to produce up-to-date figures, based on accurate sampling. The inquiry would be anonymous. When the results were known the Minister would "consider with the Association the implications of those facts in the light of the conditions which then obtain." The General Medical Services Committee has offered to coöperate in collecting fresh information, provided that the Minister agrees: (1) that the investigations shall be completed by Nov. 1 this year; (2) that the Spens report remains the basis of remuneration "until, after appropriate notice, any new basis is agreed between the Minister and the profession's representatives"; and (3) "that, if the investigations reveal inadequacy of general-practitioner remuneration or an excessive margin between their remuneration and that of other comparable professions within the National Health Service and other appropriate branches of the medical profession, the Minister will make available to general practitioners any money necessary to remedy the inadequacy or to narrow the margin." The committee has also informed the Minister of its willingness to collaborate "in a search for reasonable and prudent economies in the National Health Service."

AUREOMYCIN AND CHLOROMYCETIN

On the advice of the Medical Research Council, the Ministry of Health has decided to extend the distribution of the above antibiotics for the treatment of the following additional conditions:

'*Aureomycin.*'—Severe staphylococcal infections which have proved resistant to penicillin in adequate doses.

'*Chloromycetin.*'—Acute laryngotracheobronchitis in infants.

For the treatment of these additional conditions, the two antibiotics will be made available in hospital only.

University of Oxford

On April 27 the honorary degree of M.A. was conferred on Mr. G. T. Hollis, editor of Oxford Medical Publications.

On May 2 it was proposed to confer the honorary degree of D.C.L. on Viscount Addison, and of D.SC. on Prof. M. W. Woerdeman, of Amsterdam, and Prof. G. W. Corner, of Washington.

University of Cambridge

On April 22 the degrees of M.B., B.CHIR. were conferred by proxy on F. B. Winfield and Violet L. Lutwyche.

University of London

Mr. C. G. Rob has been appointed to the chair of surgery at St. Mary's Hospital Medical School from Oct. 1.

Mr. Rob qualified from St. Thomas's Hospital in 1937, taking his M.B. Camb. the following year, and his F.R.C.S. in 1939. In 1941 he obtained the M.CHIR. He has held surgical appointments at the Royal Victoria Hospital, Montreal, the Halifax Royal Infirmary, the Royal Surrey County Hospital, and St. Thomas's Hospital where he later became senior assistant to the surgical unit. During the late war Mr. Rob was surgical specialist to the 1st Parachute Brigade and surgeon to a field surgical unit with the rank of lieut.-colonel. He was awarded the Military Cross in 1943 and he was mentioned in despatches in 1945. In 1948 he was appointed to the university readership in surgery at St. Thomas's and elected to the staff as surgeon to outpatients. He is an examiner in surgery for the university. He has published papers on abdominal wounds, and in 1946 he delivered a Hunterian lecture at the Royal College of Surgeons.

University of Birmingham

On Thursdays, May 25 and June 1, at 4 P.M., Dr. Frances Braid will deliver the Ingleby lectures on Hypothyroidism in Childhood. Further particulars will be found in our advertisement columns.

University of Glasgow

On April 29 the following degrees were conferred:

M.D.—* J. C. Brocklehurst, A. K. Brown, D. C. Devine, T. O. P. D. Lawson, Robert Love.

Ph.D.—Alexander Hutchison.

* In absentia.

University of Edinburgh

On Wednesday, May 10, at 5 P.M., Dr. James C. White, chief of the neurological service, Massachusetts General Hospital, Harvard Medical School, is to deliver a Macarthur lecture on Neurosurgical Experience in the Treatment of Intractable Pain. The lecture will be held in the surgery lecture theatre, University New Buildings, Teviot Place, Edinburgh, and Sir James Learmonth will be in the chair.

Royal College of Physicians of London

At a comitia of the college held on April 27, with Dr. W. Russell Brain, the president, in the chair, the following were elected to the fellowship:

S. L. Ludbrook, New Zealand; T. Rowland Hill, London; E. W. Skipper, Sheffield; John Dockray, Ryde, I.W.; E. T. Baker-Bates, Liverpool; A. M. Nussey, Birmingham; R. Kemball Price, Hove; A. I. G. McLaughlin, London; W. G. A. Swan, Newcastle upon Tyne; A. W. D. Leishman, Sheffield; R. W. D. Turner, Edinburgh; J. V. Hurford, Godalming; J. R. Nassim, London; P. H. Sandifer, London; J. D. Spillane, Cardiff; A. M. G. Campbell, Bristol; H. R. Vickers, Sheffield; E. G. L. Bywaters, Taplow; Ian Macpherson, Leeds; R. E. Bonham-Carter, London; C. A. Young, London; Ralph Kauntze, London; J. W. Orr, Birmingham; H. J. Anderson, London; J. R. Squire, Birmingham; W. W. Brigden, London; F. T. G. Prunty, London; Lieut.-Colonel W. H. Hargreaves, R.A.M.C.; D. R. Cameron, York; Frank Ridehalgh, Leeds; Charles Wilcocks, London.

The following were elected to the fellowship under by-law 39b which provides for the election of non-members "who have distinguished themselves in any branch of the science or practice of medicine":

R. F. Farquharson, Toronto; N. M. Goodman, London; H. J. Ritchie, Sydney.

The Baly medal was presented to Sir Edward Mellanby, F.R.S., for his services to physiology and his work on nutrition, with particular reference to the accessory food-factors.

Dr. G. E. S. Ward was reappointed as external examiner in medicine for the Faculty of Radiologists.

The following, having satisfied the Censors' Board, were elected to the membership:

M. N. Allen, M.B. Melb., I. McL. Baird, M.B. St. And., P. F. Bartley, M.B. N.Z., P. D. Bedford, M.D. Leeds, J. T. Cahill, M.D. Melb., Harish Chandra, M.B. Bombay, R. S. C. Couch, M.B. Lond., B. N. Das Gupta, M.D. Patna, Myrddin Evans, M.B. Wales, L. C. Harris, M.D. Pretoria, K. S. Henley, M.B. Durh., I. S. Hodgson-Jones, M.B. Camb., D. V. Hubble, M.D. Lond.; Philip Hugh-Jones, M.D. Camb., P. E. Jackson, M.B. Lond., K. E. Jefferson, M.B. Camb., B. E. H. Koch, M.D. Bonn, G. D. W. McKendrick, B.M. Oxfd, E. K. Macleod, M.B. N.Z., B. G. Maegraith, M.B. Adelaide, K. S. Millingen, M.B. Sydney, J. N. Montgomery, M.B. Belf., B. P. O'Connell, M.B. Sydney, M. A. Peyman, B.M. Oxfd, R. G. Pitman, M.D. Lond., E. G. Rees, M.B. Lond., R. C. Roxburgh, M.B. Camb., R. H. Seville, M.D. Leeds, W. J. Smith, M.D. Melb., P. J. D. Snow, M.B. Manc., P. R. Swyer, M.B. Camb., W. H. Taylor, B.M. Oxfd, William Walker, M.B. St. And., N. C. T. Watford, M.B. Lond., S. C. Wigley, M.B. Melb.

Licences to practise were conferred upon the following 204 candidates (156 men and 48 women) who have passed the final examination of the Conjoint Board:

D. R. H. Addenbrooke, D. J. Adderley, Rosie Ali, Anne M. Allen, J. G. Armstrong, R. A. Arthur, Pamela M. Bacon, M. A. Baddoo, Sybille E. Baer, Harry Barkley, Cynthia Barnett, J. D. Baston, J. H. F. Batstone, Robert Baxter, P. D. Bennett, Jerzy Betkowski, Margaret E. Beynon, J. B. Blomfield, A. G. Blyth, F. G. L. Brafield, J. E. Bridger, William Brooks, A. F. W. Brown, H. B. Brown, K. M. Bryant, Janusz Buchman, A. E. R. Buckle, D. M. Burley, David Burman, R. P. Butt, B. E. Caddick, J. C. Camac, D. S. H. Cannon, J. S. Cardwell, P. M. Carpenter, C. C. D. Chandler, G. C. H. Chandler, Jack Chesover, G. E. Chorley, J. A. Churcher, H. F. Clare, A. J. Clarke, C. H. Clarke, I. S. Coleman, P. J. Cook, J. T. Cope, Elizabeth McQ. D. Craig, R. Q. Crellin, J. M. D. Crook, J. D. Crowlesmith, Pauline M. Daniels, R. G. Davies, W. H. G. Davies, K. R. J. de Belder, J. J. de Caestecker, Hugh de Glanville, F. L. A. de Marnefe, Joseph Devota, George Dougan, E. R. Duchesne, M. W. F. Dunning, A. C. de B. Eksteen, Cathleen M. Elliott, F. H. Evason, Margaret D. Findlay, John Foley, R. A. V. Forrester, E. H. Franks, John Fraser, J. W. Fullerton, I. T. Gabe, Bernard Gatoff, G. A. L. G. Glazebrook, M. P. W. Godfrey, Derek Goldman, P. C. W. Greaves, N. A. Green, Katherine A. Grice, A. W. Griffiths, H. E. D. Griffiths, B. C. Hale, Antoinette I. Hallett, M. L. Hamilton, F. G. Hardman, T. S. Hart, N. E. Harvey, Willem Hertzog, B. M. Hibbard, Iris A. Hicks, R. G. Hirons, W. G. Hodges, J. W. Hughes, F. T. Hunt, J. A. Hunt, G. B. Ihringer, Sylvia R. Ingold, Sybil E. Jacob, D. C. James, David Jenkins, F. G. Johnson, J. W. Johnson, A. G. Jones, D. K. B. Jones, Eleanor M. Jones, J. L. Jones, R. T. B. Jones, Michael Kaye, G. A. Lawrence, John Lawson-Matthew, Annie M. Legge, J. C. Leonard, G. A. Levell, Melvin Lewis, Marian H. Littlejohn, Shinmen Lin, Eunice Lockey, Merton Long, M. J. R. Mackrill, E. N. Marks, G. W.

EDWARD WILLIAM HOPE

O.B.E., M.D., D.SC. EDIN.

THE death of Professor Hope on April 27 at the age of 94 breaks one of the few remaining links with the Victorian period of environmental hygiene. The 41 years during which he held office as medical officer of health for Liverpool was a time of great activity in public health, and under his guidance there was built up on Merseyside a system of hospitals for infectious diseases, an efficient and elaborate port sanitary administration, an up-to-date school medical service, and a child-welfare department.

Edward William Hope was educated at the Royal School of Mines and the University of Edinburgh, where he graduated M.B. in 1878. In 1883 he was appointed assistant to Dr. Stopford Taylor, then M.O.H. for Liverpool. At the time of the Hamburg cholera epidemic he quickly made a reputation by his handling of an infected ship which arrived from that port. He courageously remained on the vessel and accompanied the crew when they were transferred to the port sanitary hospital. Later when plague became pandemic, though its causes were little known, he organised the first line of defence against the menace.

In 1887 he was appointed medical superintendent of the Park Hill Fever Hospital, and in 1894 he was appointed M.O.H. for Liverpool, fourth in the line of succession from Duncan the first medical officer of health in England. He took office at a time when the boundaries of the city were being greatly enlarged, and his help was more than once invited when other municipalities were pressing for similar expansion. He was an able and adroit witness when under cross-examination on such occasions or during the many housing inquiries in his own city. Probably on no subject did he carry more weight or have more experience. In 1883 there were 23,690 cellars still occupied as dwellings in Liverpool, and while Hope held office over 12,000 unfit dwellings were condemned and model tenements built in their place.

Epidemiologically his term of office was also important. He saw, and did much to promote, the eradication of typhus; indeed, his own observations anticipated in large measure the discovery of its manner of spread by lice. Largely through improvements in sanitation, his period of service coincided with a reduction in the prevalence of typhoid fever from some 1500 cases a year to a few score. With this went a reduction in infant mortality especially from zymotic diarrhœa, which resulted in the saving of an even larger number of lives. At the turn of the century, following the appointment of "women sanitary inspectors" in St. Helens, he procured the appointment, with the backing of the Rathbone family, of health visitors. Their value was at once apparent, and the provision by the city of a supply of sterilised milk greatly increased their opportunities to save the lives of artificially fed infants. Nevertheless he was always a powerful advocate of breast-feeding. His observation of the effects of intemperance in causing child neglect led him to draw attention to this evil in his annual reports. In 1916 he was asked by the Carnegie Trust to write a report on infant mortality, and the trust expressed their gratitude by presenting the money to provide the Carnegie welfare centre adjacent to the Liverpool Maternity Hospital.

An outbreak of smallpox in 1902, following repeated importations from Boston and elsewhere, led to considerable expansion of the city's fever hospitals, especially at Fazakerley. Hope contested vigorously the concept of the then officers of the Local Government Board that aerial convection was responsible for its spread. A powerful rejoinder to an official report by the board's officer was considered by many to have given this theory its quietus.

From early days Dr. Hope had been associated with the university movement. In 1886 he became lecturer on public health in the university college at Liverpool, and he was appointed professor of public health in the college when it was affiliated to the Victoria University, and later in the University of Liverpool when it obtained its charter in 1903. He played a large part in the foundation of the Liverpool School of Hygiene and he was the first to arrange special courses for health visitors. He examined in public health for the Universities of Cambridge, Belfast, Manchester, Edinburgh, and London.

Throughout his work as M.O.H., Dr. Hope was on the best of terms with his medical colleagues, and this good feeling was expressed by his appointment as president of the Liverpool Medical Institution. He also served as president of the Society of Medical Officers of Health. He was appointed O.B.E. in 1918. In 1924 he retired, but new editions of his textbooks had still to be prepared and seen through the press, and in 1931 in his *Health at the Gateway* he retold his own experiences and described the special health problems of a city whose staple industry is shipping. Active in mind and body, with charm, ability, and force of character, he will long be remembered as one who played a great part in converting the black spot on the Mersey into a reasonably healthy city.

In 1899 Dr. Hope married C. Rennie, daughter of John Bowring, and a sister of a former lord mayor of Liverpool. They had a son and two daughters.

Wednesday, 10th

INSTITUTE OF LARYNGOLOGY AND OTOLOGY
9.30 A.M. Mr. A. C. Deverell: Relationship of Dental Disease to Diseases of the Throat, Nose, and Ear.

INSTITUTE OF PSYCHIATRY
4.30 P.M. (Maudsley Hospital, S.E.5.) Dr. Denis *Hill: Post-graduate lecture-demonstration.*

LONDON [illegible] SOCIETY
3 P.M. [illegible] Winchmore Hill, N.19.) Clinical

Thursday, 11th

ROYAL COLLEGE OF PHYSICIANS
5 P.M. Dr. Clark-Kennedy: The Patient and his Disease. (Last *Croonian lecture.)*

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
5 P.M. Mr. H. F. Moseley: Ruptures of the Rotator Cuff. (Hunterian lecture.)

INSTITUTE OF DERMATOLOGY
5 P.M. Dr. Brian Russell: Skin Diseases caused by Light.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL, S.W.1
4.30 P.M. Dr. Denis Williams: Neurology demonstration.

HONYMAN GILLESPIE LECTURE
5 P.M. (University New Buildings, Teviot Place, Edinburgh.) Dr. R. C. L. Batchelor: Recent Developments in Venereology.

Friday, 12th

ROYAL COLLEGE OF PHYSICIANS
5 P.M. Prof. G. W. Pickering: Cardiac Failure.

UNIVERSITY OF LONDON
5.30 P.M. (University College, W.C.1.) Prof. G. B. Wislocki (Harvard University): Cytology and *Histochemistry* of the Uterus and Placenta. (First of three lectures.)

MAIDA VALE HOSPITAL FOR NERVOUS DISEASES, W.9
5 P.M. Dr. Douglas McAlpine: Clinical neurological demonstration.

BRITISH ASSOCIATION OF PHYSICAL MEDICINE
5.30 P.M. (Royal College of Surgeons.) Dr. Frank H. Krusen (Mayo Clinic): Work of the Baruch Committee.

Saturday, 13th

SOUTH-EAST METROPOLITAN REGIONAL TUBERCULOSIS SOCIETY
11 A.M. (Kettlewell Hospital, Swanley, Kent.) Dr. E. L. Sandiland: Is Your Pneumoperitoneum Really Necessary?

Notes and News

REMUNERATION OF GENERAL PRACTITIONERS

The Minister of Health is proposing to make a further inquiry into the professional incomes and expenses of general practitioners, on the basis of information provided by executive councils and the Inland Revenue authorities. At a meeting on April 3 with representatives of the General Medical Services Committee, the Minister stated that the Government's "wage-freeze" policy could not be disregarded, and he was not prepared to make any increase in the central pool on the facts before him. The inquiry into payments would relate to earnings in the year ended March 31, 1950; this information would be obtained from executive councils. Secondly, in order to discover what the practice expenses had proved to be in the National Health Service, the Inland Revenue authorities would be asked (if the profession agreed) to produce up-to-date figures, based on accurate sampling. The inquiry would be anonymous. When the results were known the Minister would "consider with the Association the implications of those facts in the light of the conditions which then obtain." The General Medical Services Committee has offered to coöperate in collecting fresh information, provided that the Minister agrees: (1) that the investigations shall be completed by Nov. 1 this year; (2) that the Spens report remains the basis of remuneration "until, after appropriate notice, any new basis is agreed between the Minister and the profession's representatives"; and (3) "that, if the investigations reveal inadequacy of general-practitioner remuneration or an excessive margin between their remuneration and that of other comparable professions within the National Health Service and other appropriate branches of the medical profession, the Minister will make available to general practitioners any money necessary to remedy the inadequacy or to narrow the margin." The committee has also informed the Minister of its willingness to collaborate "in a search for reasonable and prudent economies in the National Health Service."

AUREOMYCIN AND CHLOROMYCETIN

On the advice of the Medical Research Council, the Ministry of Health has decided to extend the distribution of the above antibiotics for the treatment of the following additional conditions:

'*Aureomycin*.'—Severe staphylococcal infections which have proved resistant to penicillin in adequate doses.

'*Chloromycetin*.'—Acute laryngotracheobronchitis in infants.

For the treatment of these additional conditions, the two antibiotics will be made available in hospital only.

University of Oxford

On April 27 the honorary degree of M.A. was conferred on Mr. G. T. Hollis, editor of Oxford Medical Publications.

On May 2 it was proposed to confer the honorary degree of D.C.L. on Viscount Addison, and of D.SC. on Prof. M. W. Woerdeman, of Amsterdam, and Prof. G. W. Corner, of Washington.

University of Cambridge

On April 22 the degrees of M.B., B.CHIR. were conferred by proxy on F. B. Winfield and Violet L. Lutwyche.

University of London

Mr. C. G. Rob has been appointed to the chair of surgery at St. Mary's Hospital Medical School from Oct. 1.

Mr. Rob qualified from St. Thomas's Hospital in 1937, taking his M.B. Camb. the following year, and his F.R.C.S. in 1939. In 1941 he obtained the M.CHIR. He has held surgical appointments at the Royal Victoria Hospital, Montreal, the Halifax Royal Infirmary, the Royal Surrey County Hospital, and St. Thomas's Hospital where he later became senior assistant to the surgical unit. During the late war Mr. Rob was surgical specialist to the 1st Parachute Brigade and surgeon to a field surgical unit with the rank of lieut.-colonel. He was awarded the Military Cross in 1943 and he was mentioned in despatches in 1945. In 1948 he was appointed to the university readership in surgery at St. Thomas's and elected to the staff as surgeon to outpatients. He is an examiner in surgery for the university. He has published papers on abdominal wounds, and in 1946 he delivered a Hunterian lecture at the Royal College of Surgeons.

University of Birmingham

On Thursdays, May 25 and June 1, at 4 P.M., Dr. Frances Braid will deliver the Ingleby lectures on Hypothyroidism in Childhood. Further particulars will be found in our advertisement columns.

University of Glasgow

On April 29 the following degrees were conferred:

M.D.—* J. C. Brocklehurst, A. K. Brown, D. C. Devine, T. O. P. D. Lawson, Robert Love.

Ph.D.—Alexander Hutchison.

* In absentia.

University of Edinburgh

On Wednesday, May 10, at 5 P.M., Dr. James C. White, chief of the neurological service, Massachusetts General Hospital, Harvard Medical School, is to deliver a Macarthur lecture on Neurosurgical Experience in the Treatment of Intractable Pain. The lecture will be held in the surgery lecture theatre, University New Buildings, Teviot Place, Edinburgh, and Sir James Learmonth will be in the chair.

Royal College of Physicians of London

At a comitia of the college held on April 27, with Dr. W. Russell Brain, the president, in the chair, the following were elected to the fellowship:

S. L. Ludbrook, New Zealand; T. Rowland Hill, London; E. W. Skipper, Sheffield; John Dockray, Ryde, I.W.; E. T. Baker-Bates, Liverpool; A. M. Nussey, Birmingham; R. Kemball Price, Hove; A. I. G. McLaughlin, London; W. G. A. Swan, Newcastle upon Tyne; A. W. D. Leishman, Sheffield; R. W. D. Turner, Edinburgh; J. V. Hurford, Godalming; J. R. Nassim, London; P. H. Sandifer, London; J. D. Spillane, Cardiff; A. M. G. Campbell, Bristol; H. R. Vickers, Sheffield; E. G. L. Bywaters, Taplow; Ian Macpherson, Leeds; R. E. Bonham-Carter, London; C. A. Young, London; Ralph Kauntze, London; J. W. Orr, Birmingham; H. J. Anderson, London; J. R. Squire, Birmingham; W. W. Brigden, London; F. T. G. Prunty, London; Lieut.-Colonel W. H. Hargreaves, R.A.M.C.; D. R. Cameron, York; Frank Ridehalgh, Leeds; Charles Wilcocks, London.

The following were elected to the fellowship under by-law 39b which provides for the election of non-members "who have distinguished themselves in any branch of the science or practice of medicine":

R. F. Farquharson, Toronto; N. M. Goodman, London; H. J. Ritchie, Sydney.

The Baly medal was presented to Sir Edward Mellanby, F.R.S., for his services to physiology and his work on nutrition, with particular reference to the accessory food-factors.

Dr. G. E. S. Ward was reappointed as external examiner in medicine for the Faculty of Radiologists.

The following, having satisfied the Censors' Board, were elected to the membership:

M. N. Allen, M.B. Melb., I. McL. Baird, M.B. St. And., P. F. Bartley, M.B. N.Z., P. D. Bedford, M.D. Leeds, J. T. Cahill, M.D. Melb., Harish Chandra, M.B. Bombay, R. S. C. Couch, M.B. Lond., B. N. Das Gupta, M.D. Patna, Myrddin Evans, M.B. Wales, L. C. Harris, M.D. Pretoria, K. S. Henley, M.B. Durh., I. S. Hodgson-Jones, M.B. Camb., D. V. Hubble, M.D. Lond., Philip Hugh-Jones, M.D. Camb., P. E. Jackson, M.B. Lond., K. E. Jefferson, M.B. Camb., B. E. H. Koch, M.D. Bonn, G. D. W. McKendrick, B.M. Oxfd, E. K. Macleod, M.B. N.Z., B. G. Maegraith, M.B. Adelaide, K. S. Millingen, M.B. Sydney, J. N. Montgomery, M.B. Belf., B. P. O'Connell, M.B. Sydney, M. A. Peyman, B.M. Oxfd, R. G. Pitman, M.D. Lond., E. G. Rees, M.B. Lond., R. C. Roxburgh, M.B. Camb., R. H. Seville, M.D. Leeds, W. J. Smith, M.D. Melb., P. J. D. Snow, M.B. Manc., P. R. Swyer, M.B. Camb., W. H. Taylor, B.M. Oxfd, William Walker, M.B. St. And., N. C. T. Watford, M.B. Lond., S. C. Wigley, M.B. Melb.

Licences to practise were conferred upon the following 204 candidates (156 men and 48 women) who have passed the final examination of the Conjoint Board:

D. R. H. Addenbrooke, D. J. Adderley, Rosie Ali, Anne M. Allen, J. G. Armstrong, R. A. Arthur, Pamela M. Bacon, M. A. Baddoo, Sybille E. Baer, Harry Barkley, Cynthia Barnett, J. D. Baston, J. H. F. Batstone, Robert Baxter, P. D. Bennett, Jerzy Betkowski, Margaret E. Beynon, J. B. Blomfield, A. G. Blyth, F. G. L. Brafield, J. E. Bridger, William Brooks, A. F. W. Brown, H. B. Brown, K. M. Bryant, Janusz Buchman, A. E. R. Buckle, D. M. Burley, David Burman, R. P. Butt, B. E. Caddick, J. C. Camac, D. S. H. Cannon, J. S. Cardwell, P. M. Carpenter, C. C. D. Chandler, G. C. H. Chandler, Jack Chesover, G. E. Chorley, J. A. Churcher, H. F. Clare, A. J. Clarke, C. H. Clarke, I. S. Coleman, P. J. Cook, J. T. Cope, Elizabeth McQ. D. Craig, R. Q. Crellin, J. M. D. Crook, J. D. Crowlesmith, Pauline M. Daniels, R. G. Davies, W. H. G. Davies, K. R. J. de Belder, J. J. de Caestecker, Hugh de Glanville, F. L. A. de Marnefe, Joseph Devota, George Dougan, E. R. Duchesne, M. W. F. Dunning, A. C. de B. Eksteen, Cathleen M. Elliott, F. H. Evason, Margaret D. Findlay, John Foley, R. A. V. Forrester, E. H. Franks, John Fraser, J. W. Fullerton, I. T. Gabe, Bernard Gatoff, G. A. L. G. Glazebrook, M. P. W. Godfrey, Derek Goldman, P. C. W. Greaves, N. A. Green, Katherine A. Grice, A. W. Griffiths, H. E. D. Griffiths, B. C. Hale, Antoinette I. Hallett, M. L. Hamilton, F. G. Hardman, T. S. Hart, N. E. Harvey, Willem Hertzog, B. M. Hibbard, Iris A. Hicks, R. G. Hirons, W. G. Hodges, J. W. Hughes, F. T. Hunt, J. A. Hunt, G. B. Ihringer, Sylvia R. Ingold, Sybil E. Jacob, D. C. James, David Jenkins, F. G. Johnson, J. W. Johnson, A. G. Jones, D. K. B. Jones, Eleanor M. Jones, J. L. Jones, R. T. B. Jones, Michael Kaye, G. A. Lawrence, John Lawson-Matthew, Annie M. Legge, J. C. Leonard, G. A. Levell, Melvin Lewis, Marian H. Littlejohn, Shinmen Lin, Eunice Lockey, Merton Long. M. J. R. Mackrill, E. N. Marks, G. W.

Marsh, Nancy A. H. Marston, Frances E. Mather, J. R. M. Mathieson, J. M. Mayer, A. P. Melgrave, A. J. Merrifield, W. E. Miall, J. L. Milligan, Mary Mitchell, R. E. Molloy, Pamela M. Moody, Rumesh Chandra Nauth-Misir, *Patricia L. Obee, Joan E. M. O'Brien.* D. F. O'Malley, J. H. Owen, J. B. Parsons, D. J. Pearce, A. O, Peters, Anne M. Phillips, G. F. M. Pierce, Theresa Posner, R. J. Powell, Elma P. Pridham, Patience Proby, R. J. H. Raines, W. D, Ratnavale, A. M. Reader, Marion E. Record, J. H. Rees, B. G. Reynolds, C. S. Rhodes, J. A. Richards, D. M. Richardson, D. McL. Riddell, J. MacL. G. Ritchie, A. W. Roberts, Margaret G. Roberts. Margaret E. Robson, Israel Rocker, Thea G. T. Rose, Margaret M. Sander, J. R. Saunders, Diana M. Scott, A. L. Slater, B. O. Smith, Florence L. Smith, G. W. Smith, S. R. Somers, P. R. Sowerby, Gwyneth M. Stevens, Leonard Tann, J. S. Taylor, Eira Thomas, M. G. Thompson, Eleanor M. R. Till, P. A. Van der Merwe, C. B. Vaughan, M. G. S. Vercoe, D. W. Verity, M. H. Vickery, A. J. Wainwright, J. C. N. Wakeley, *Dorothy C. Wall*, J. St. G. Warmann, Mary D. B. Warnock, Brian Waters, Paula M. Watkin, Mary D. Watkins, Sheila M. Watts, Daphne E. Webber, Mary M. Weeks, Otto Weiss, Josephine P. Werren, W. N. Whamond, A. E. Wheatley, M. L. Wheatley, R. J. M. Whittle, Alfred Wiener, A. O. Wilkey, P. O. Williams, V. A. Wills, Kathleen M. Witham, R. F. Wright.

Diplomas were conferred on those named in the report of the meeting of the College of Surgeons in our issue of April 22 (p. 791).

Laboratory Animals Bureau Congress

Over 400 technicians attended this congress which took place at the Royal Veterinary College, London, on March 30 and 31. During the meeting the Animal Technicians Association was formed, under the presidency of Mr. A. S. Parkes, SC.D., F.R.S. The hon. secretary is Mr. A. E. Mundy, Research Institute, Royal Veterinary College, Royal College Street, London, N.W.1, from whom further details may be had.

North-West Metropolitan Board

At a meeting on April 17, the North-West Metropolitan Regional Hospital Board approved in principle the re-siting of the West End Hospital for Nervous Diseases "as a matter of urgency." The board agreed that at the London Lock Hospital inpatient accommodation should be provided for male patients suffering from venereal disease, and that both male and female outpatient clinics should be continued. The board also agreed that in advertising for a part-time consultant pædiatrician at the Royal London Homœopathic Hospital, no reference should be made to a need for candidates to have had experience in homœopathy. It adopted the following resolution on study leave: "That in considering applications for grants of study leave with pay for preparing for appropriate higher qualifications, grants be normally restricted to the registrar grades and granted up to a maximum of 14 days, including the period of the actual examination."

Czechoslovakia Withdraws from W.H.O.

The government of Czechoslovakia notified the World Health Organisation on April 21 that it "no longer considers itself a member of the Organisation." In a letter to Dr. Broek Chisholm, director-general of W.H.O., Mr. Viliam Siroky, vice-president of the Council of Ministers and minister for foreign affairs, states that, in the opinion of the Czech government, W.H.O. does not fulfil the aims and principles of its constitution, which Czechoslovakia signed and ratified. The letter adds: "The fundamental objectives laid down in the W.H.O. constitution have remained a dead letter. Moreover, the Organisation is subject to political influences which lead to discrimination against member States, among them Czechoslovakia. Developments within the World Health Organisation thus contradict the principles of the constitution, adherence to which was the essential pre-condition for Czechoslovak participation."

World Health Assembly

The United Kingdom's chief delegate to the World Health Assembly, which opens in Geneva on May 8, will be Dr. Melville Mackenzie, of the Ministry of Health. The other delegates will be Dr. Wilson Rae, deputy chief medical officer, Colonial Office, and Mr. T. Lindsay, of the Ministry of Health. Accompanying them as advisers will be Sir John Charles, chief medical officer designate, Ministry of Health; Sir Andrew Davidson, chief medical officer, Department of Health for Scotland; Dr. R. H. Barrett and Mr. F. Mells, of the Ministry of Health; Dr. W. S. Maclay, senior commissioner, Board of Control; Mr. A. E. Joll, of the General Register Office; Dr. Percy Stocks, chief medical statistician, General Register Office; and Miss S. N. Udell, chief nursing officer, Colonial Office. Dr. Barrett is acting as secretary to the delegation. Dr. Melville Mackenzie will also attend a meeting of the executive board of the World Health Organisation which will follow the World Assembly.

University of Wisconsin

Dr. A. M. MacKay, formerly first assistant in the Nuffield department of anæsthetics at Oxford, has been appointed to the chair of anæsthetics.

Royal Society

Prof. C. F. Cori, professor of medicine at Washington University, St. Louis, has been elected a foreign member of the society for his work on metabolism of carbohydrates in the animal body.

First International Pharmacopœia

Last Monday the W.H.O. expert committee which has been working on the first *International Pharmacopœia*, announced in New York the completion of the English edition. The *Times* (May 2) reports that the book, dealing with about two hundred drugs in general use, will be issued later this year when the French text is ready. A Spanish translation will follow. The chairman of the committee is Dr. C. H. Hampshire, secretary of the British Pharmacopœia Commission.

Charges for Spectacles

From last Monday, May 1, the varieties of spectacle frames supplied without charge under the National Health Service were reduced to four; and for the range of frames towards which the patient is required to contribute the charge (previously *1s.–8s.*) was raised to *2s.–12s. 3d.* The contribution from the patient towards the cost of repair and replacement in the contributory range is correspondingly increased, and a charge will be made for replacement and repair of frames now coming into this range.

Dr. R. R. Trail has been appointed a chevalier of the Legion of Honour of the French Republic.

CORRIGENDUM: *Penicillin in Uncomplicated Gonorrhœa.*—The second paragraph of Dr. Macdonald's letter last week (p. 833) should have begun as follows: "Owing to the anatomy of the area, every case is, to a greater or lesser extent, a closed infection, which would account for the infective latency which undoubtedly prevails for a time after penicillin therapy."

Appointments

BRETT, G. Z., M.D. Lwow: physician i.c. mass-radiography units, North-West Metropolitan Region.
CLARKE, W. E., M.D. Lond., M.R.C.P.: physician, Highlands Hospital, London.
CUDDIGAN, J. P., M.B. N.U.I., D.A.: consultant anæsthetist, Holloway Sanatorium, Virginia Water, Surrey.
HARLEY, DAVID, M.D., B.SC. Edin.: consultant physician i.c. clinic for allergic conditions, Central Middlesex Hospital.
MAGRATH, DONALD, M.B. Birm., D.P.H., D.P.M.: consultant psychiatrist, Botleys Park Hospital, Chertsey, Surrey.
MOORE, J. C. G., B.A., M.B. Dubl., F.R.C.S.E., D.O.M.S.: consultant ophthalmic surgeon, Edgware General Hospital.
SHANLY, H. M. G., M.B. Lond.: M.O., Colonial Service, Kenya.

Appointed Factory Doctors:
PARKES, TREVOR, M.B. Lond.: Rye district, Sussex.
PEARSON, G. H., M.R.C.S.: Cranborne district, Dorset.

Births, Marriages, and Deaths

BIRTHS

BARRY.—On April 27, in Edinburgh, the wife of Dr. C. T. Barry—a daughter.
BRIERLEY.—On April 28, at Worcester, the wife of Dr. D. M. Brierley—a son.
CASEY.—On April 28, at Congleton, Cheshire, the wife of Dr. M. B. Casey—a daughter.
GIBBINS.—On April 24, in Birmingham, the wife of Mr. R. E. Gibbins, F.R.C.S.—a daughter.
MONYPENNY.—On April 11, at Sheffield, to Dr. Isabelle Monypenny (née Little), wife of Dr. E. R. Monypenny—a son.
RODGERS.—On April 22, in Liverpool, the wife of Dr. T. Stanley Rodgers—a son.

MARRIAGES

CURTIS—MAYNARD.—On April 22, Derek Curtis, M.R.C.S., to Jean Maynard.

DEATHS

BOWER.—On April 24, John Alexander Bower, M.B. Edin., aged 83.
GORDON.—On April 26, at Bath, Ronald Grey Gordon, M.D., D.SC. Edin., F.R.C.P.E.
HOPE.—On April 27, at Caldy, Cheshire, Edward William Hope, O.B.E., M.D., D.SC. Edin., aged 95.
WAKELY.—On April 21, at Creech St. Michael, Taunton, Alfred Stewart Wakely, M.C., M.B. Lond., D.P.H.

CARDIAC FAILURE *

BASIL THOMAS PARSONS-SMITH
M.D. Lond., F.R.C.P.
CONSULTING PHYSICIAN, NATIONAL HEART HOSPITAL, LONDON

IN 1581 Lord Lumley and Richard Caldwell, M.D., a fellow of the college, were granted permission by her Majesty Queen Elizabeth, under the Broad Seal, to found a surgical lecture in the College of Physicians and to endow it in perpetuity. For many years the Lumleian lectureship was a life appointment; then for a short period it was reduced to five years; and since 1825 the lecturer has been nominated annually.

William Harvey commenced his Lumleian lectures at the college in April, 1616, and is generally supposed to have expounded, on that occasion, those original and complete views of the circulation of the blood which have made him the glory and the honour of British physicians. The compelling influence of Harvey can be traced throughout the whole history of the lectureship. When its conditions were reconstituted in 1827, its first holder, Peter Mere Latham, took for his subject Some Diseases of the Heart. In 1829 John Elliotson spoke on the Recent Improvements in the Art of Distinguishing the Various Diseases of the Heart, a subject in which he was singularly proficient, being one of the first British physicians to appreciate the value of the stethoscope. In more recent times a cardiological flavour has been imparted to this lectureship in the contributions of Osler, Mitchell Bruce, Horder, Carey Coombs, Parkinson, Crighton Bramwell, Geoffrey Evans, and Maurice Campbell.

* * *

As an introduction to the modern conception of cardiac failure, certain of the pioneer theories deserve special mention.

BACK PRESSURE AND FORWARD FAILURE

In the early part of last century, James Hope (1832) formulated the so-called back-pressure theory. He began by referring to the "order of succession in which the several compartments of the heart are rendered hypertrophous by an obstacle before them in the course of circulation." After which he said:

> "As an obstacle to the circulation operates on the heart in a retrograde direction, the cavity situated immediately behind it is the first to suffer from its influence.
>
> "When the distending pressure of the blood preponderates over the power of the (left) ventricle, its contents, from not being duly expelled, constitute an obstacle to the transmission of the auricular blood; hence the auricle becomes over-distended, and the obstruction may be propagated backwards through the lungs to the right side of the heart and there occasion the same series of phenomena.
>
> "When the mitral orifice is contracted . . . the left auricle, having to struggle against the contracted valve in front, and also to sustain the distending pressure of the blood flowing in from the lungs, invariably becomes thickened and dilated; the engorgement, extending backwards through the lungs to the right ventricle, occasions its hypertrophy and dilatation, the lungs suffering in pre-eminent degree.
>
> "When the impediment to the circulation is primitively seated in the lungs, the right ventricle, situated immediately behind them, is the first to experience its influence; and when the cavity is so far overpowered by the distending pressure of the blood as to be incapable of adequately expelling its contents, the obstruction extends to the auricle.
>
> "Obstruction in the right auricle, whether from this or other cause, presents an obstacle to the return of the venous blood and therefore ultimately causes retardation throughout the whole venous system; nor is this all; for the retardation is propagated throughout the capillaries to the arterial system and thus at length returns in a circle to the heart."

Hope's classical hypothesis was modified by William Stokes (1854), who stressed the significance of myocardial incompetence in cases of valvular heart-disease, thus incidentally originating the forward-failure theory which received further recognition by cardiologists a generation later. A brief extract from his treatise on *Diseases of the Heart and Aorta* summarises his views on cardiac failure:

> "It too often happens," he said, "when the existence of a valvular disease is determined, that great labour is expended in ascertaining the exact seat and nature of the affection. Long and careful examinations are made to determine whether the disease exists at the right or left side of the heart; whether it be a lesion of the mitral, tricuspid, or the semi-lunar valves; a contraction; an ossification; a permanent patency or warty excrescence. Now, though in some, we might say in many cases, these cases may be resolved with considerable accuracy, it is also true that in a large number their determination is of comparatively trifling importance; and the two great practical points to be attended to are, first, whether the murmurs proceed from an organic cause, and next, what is the vital and physical condition of the muscular portions of the heart; for it is upon these points that prognosis and treatment must entirely depend.
>
> "The practical physician, having satisfied himself that a valvular disease exists, will not devote too much time in ascertaining its exact nature; but he will examine into the vital and mechanical state of the heart's cavities. He will ascertain the amount of vigour of the heart, whether its force is above or below the natural standard."

The forward-failure theory continued to attract interest, and in the early years of this century clinicians began to assess cardiac failure in terms of myocardial incompetence. Their primary concern was to estimate the degree to which the heart's driving-power and output were impaired, and in so doing they discounted the significance of the back-pressure effects hitherto generally accepted.

James Mackenzie, whose investigations will be the pride of cardiologists for all time, was a staunch advocate of the forward-failure theory. He regarded breathlessness, dropsy, engorgement of the liver, and renal congestion as indications of a deficient output into the systemic circulation, a similar discrepancy in the lesser circuit being responsible for stasis and œdema in the lungs. Mackenzie's views were approved in broad principle by his contemporaries in this country, and it is noteworthy that his distinguished friend, Thomas Lewis, summarised his interpretation of cardiac failure in the following terms:

> "Breathlessness, the first indication of failure, is due to a deficiency in flow of aerated blood to the head and neck. When the output declines, blood begins to collect at the venous side and the patient manifests signs of congested veins, enlargement of the liver, cyanosis, scanty urine, ascites and dropsy of the lower members and congestion and œdema of the lungs."

VENOUS PRESSURE

During recent years, our ideas of cardiac failure problems have been fundamentally revised, partly through the physiological work of Starling (1918) and partly through the researches of Haldane, Thomas Lewis, Lorraine Smith, McMichael, William Evans, and Sharpey-Schafer in this country, of Plesch in Germany, of Krogh and Lindhard in Denmark, of Henderson, Marshall, Grollman, Fishberg, and Harrison in America, and of many others.

Starling's monumental study of the circulatory mechanism is a landmark in cardiology. He showed that, within reasonable limits, the heart's output remained constant whatever the level of the arterial blood-pressure, and that, with an increased venous inflow, the output was proportionately augmented. He held that the compensatory mechanism governing the range of the cardiac output originated in the muscle-fibres themselves, his results being similar whether the nervous connections were severed or intact. He regarded the lengthening of the muscle-fibres as the primary manifestation of myocardial fatigue, and he found that the contractile energy of the heart increased in direct proportion to the lengthening of the fibres. His final conclusion was that lengthening of the myocardial muscle-fibres made them capable of more work, the cardiac output remaining constant at the expense of the greater diastolic volume and the raised venous pressure which usually characterise failure.

---

* The Lumleian lectures delivered at the Royal College of Physicians on April 11 and 13, 1950.

As opposed to the back-pressure and the forward-failure theories, in both of which a raised venous pressure was regarded as a passive development, the modern interpretation, based on Starling's law of the heart, is that the venous filling pressure plays an active part in regulating the range of the cardiac output, and that in a failing heart the rise of venous pressure is, for a time, a compensatory mechanism.

McMichael (1938) correlated the venous pressure and the cardiac output in 24 patients with varying degrees of failure and his conclusions were as follows:

> "In the first stages of cardiac failure, the cardiac output falls with no significant change in the venous pressure. Mere lack of forward pressure, therefore, does not raise the venous pressure. The next point of importance is that, when the venous pressure does rise, the cardiac output tends to be higher than in the previous stage of the disease when the venous pressure was normal. In the later stages of failure, the heart becomes less and less responsive to a rise in the venous pressure and its output undergoes gradual diminution in proportion to the degree to which the failure process has proceeded. Thus the severity of cardiac failure bears a much closer relationship to the inability of the heart to increase its output in response to a venous pressure rise than to any change in the absolute value of the output at rest."

McMichael put forward two explanations of the raised venous pressure in congestive heart-failure: (1) venomotor changes, and (2) changes in the blood volume. He referred to the venous constriction induced by sympathetic-nerve stimulation and to the contraction which veins undergo in certain well-known vasomotor reflexes elicited by asphyxia, oxygen-lack (Gollwitzer-Meier 1931), and changes in pressure in the carotid sinus (Heymans et al. 1930). He thought it probable that analogous adjustments of venous capacity occurred in the presence of a failing circulation, and that the venous pressure near the heart was raised thereby. He also commented on the increase in the blood volume seen in cardiac congestion, which was first measured by Lorraine Smith (1902). In McMichael's opinion, an increase of the volume of blood in the veins, by relatively diminishing their capacity, probably contributes to the raised venous pressure of congestive heart-failure.

Acute Heart-failure

It will be convenient to divide cardiac failure into three clinical types—acute, congestive, and ischæmic—and to consider acute heart-failure first.

The numerous conditions sometimes directly associated with such failure include diphtheria, pneumonia, massive pulmonary embolism, pericardial effusion, paroxysmal tachycardia, angina pectoris, and coronary thrombosis. In all of these the clinical picture is likely to be complicated by collapse of the peripheral vascular system, the signs of which include pallor, a cold clammy skin, collapsed veins, and a rapid low-tension pulse.

Analysing 200 cases of *diphtheritic myocarditis*, Neubauer (1945) recorded a 3% incidence of auricular fibrillation, with partial auriculoventricular block in four of the patients and complete block in the other two. Burkhardt et al. (1938) described eleven fatal cases of auriculoventricular dissociation in diphtheria, some of which developed terminal ventricular tachycardia. Bourne (1940) described one case of diphtheritic myocarditis with auricular fibrillation in a woman aged 79. Cookson (1945) analysed eighty-three cases of diphtheria, in sixty-three (76%) of which the cardiograms were abnormal, ten showing some defect of conduction, other discrepancies including inversion of the T waves in one or more leads, displacement of the S-T segments, slurring and widening of the Q R S complexes, and bizarre P waves.

Acute cardiac failure as a complication of *pneumonia* has long been recognised clinically and confirmed post mortem.

Saphir and Amromin (1948) correlated the clinical and the necropsy findings in sixty-seven patients who died following pneumonia. In twenty-six cases they found histological evidence of recent myocarditis, and in fifteen others they observed degenerative changes in the shape of cloudy swelling and fatty degeneration of the myocardial fibres. Half the patients of the group died, and the authors commented on the lack of relation between the extent of the pulmonary affection and the degree of the myocardial changes.

It remains to mention acute *cor pulmonale*, a condition described by McGinn and White in 1935, the essential features of which include a sudden rise of blood-pressure in the pulmonary circuit, with dilatation of the right ventricle, usually caused by massive embolic obstruction of the pulmonary circulation.

The symptoms of acute cor pulmonale closely resemble those of coronary occlusion. For their differential diagnosis Rae Gilchrist (1950) has emphasised certain features:

1. The symptoms in massive pulmonary embolism reach their maximum intensity at once, whereas in cardiac infarction there is often delay before they do so.
2. The pain in massive pulmonary embolism is widespread, across the front of the chest, occasionally lateral and without characteristic radiation, whereas the pain in acute coronary occulsion is usually central and retrosternal, or occasionally epigastric.
3. In pulmonary embolism breathlessness is sudden and intense, whereas in cardiac infarction it is rarely conspicuous in the early stages of the illness.

Physical examination may reveal unequivocal evidence of pulmonary hypertension with right heart-failure, and the pattern of the cardiogram is as a rule pathognomonic. Reliable physical signs include triple rhythm and jugular stasis; also variable pulsation, accentuation of the second sound, a systolic murmur, and a friction rub over the area of the pulmonary artery. The dilatation of the right ventricle and of the pulmonary artery can best be demonstrated by radioscopy, which may reveal elevation of the diaphragm on the affected side, and, in due course, the site and the extent of the pulmonary infarction.

The cardiographic discrepancies which follow massive obstruction of the pulmonary circulation have been widely studied and the investigations of Paul Wood (1948) have established certain changes as characteristic of the disease and incidentally of right ventricular stress. These changes include prominent S waves in lead I, deep Q waves and inverted T waves in lead III, augmented P waves in lead II, absent Q waves and diphasic T waves or depression of the S-T segments in lead II, inverted T waves in lead V_1 to V_3 or V_4 and rarely, right bundle-branch block.

Congestive Heart-failure

The term congestive heart-failure refers to conditions of circulatory embarrassment in which abnormalities of the ventricular output are associated with congestion in the systemic, pulmonary, and portal circuits, singly or in combination.

In recent years certain valuable methods have been evolved to implement the principle enunciated by Fick in 1870—namely, that the cardiac output (in litres per minute) could be determined by dividing the rate of oxygen-consumption (in c.cm. per minute) by the amount of oxygen taken up by each litre of blood passing through the lungs.

The first successful application of Fick's formula was achieved by Marshall and Grollman (1928). Their method was based on the fact that acetylene is soluble in the blood (740 c.cm. in a litre) and that, by breathing an acetylene-air-oxygen mixture and analysing samples of blood at intervals, the relative rates of absorption of acetylene and oxygen can be estimated. From these findings an accurate estimate can be made of the amount of oxygen taken up by each litre of blood in its passage through the lungs.

Harrison et al. (1934) investigated a controlled series of cases by the acetylene method of Grollman et al. (1933) and concluded that:

1. The cardiac output per minute per square metre of patients with congestive heart-failure is usually lower than that of persons without cardiac disease, but may be within a normal range.
2. The disappearance of congestive heart-failure may be associated with an increase, a decrease, or no change in the output per minute, but the output per beat usually increases with clinical improvement.

These somewhat divergent findings convinced Harrison that there is no definite relation between the severity of the cardiac failure and the degree of diminution of the cardiac output. He suggested the intervention of compensatory mechanisms—particularly a rise in the venous pressure—as being instrumental in maintaining, to a varying degree, the output range of the failing heart; and this conclusion was later confirmed by Fishberg (1940).

To obviate the difficult measurement of the arteriovenous oxygen difference entailed by the respiratory technique, McMichael and Sharpey-Schafer (1944) employed the direct method of cardiac catheterisation for the analysis of the blood in the right auricle. They carried out a series of tests on normal male volunteers, and in calculating the arteriovenous oxygen difference they assumed the arterial blood to be 95% saturated. From their results they reached several important conclusions:

1. As compared with its volume in the erect position, the cardiac output increases by an average of 30% on lying down.
2. As expected from Starling's law, a reduction in right auricular pressure (by venesection or by cuffs on the thighs at diastolic pressure) leads to a fall in the cardiac output, while a rise in right auricular pressure (by saline infusion) is accompanied by an increase in cardiac output.
3. The average normal resting cardiac output in the recumbent position is 5·3 litres per minute, but in the standing position it is 25% less—i.e., 4 litres.

Further investigations enabled McMichael (1948) to recognise that venous congestion may arise not only in conditions where the output is reduced but also in conditions where the output is high. He divided cardiac failure with venous congestion into two groups: (1) failure with a low output, in hypertensive, ischæmic, and valvular heart-disease, and (2) failure with a high output, in conditions such as anæmia, emphysema, arteriovenous aneurysm, and Paget's disease, in all of which venous pressure must be maintained at a high level if adequate compensation is to be preserved.

LEFT HEART-FAILURE

With certain exceptions—notably acute rheumatic carditis, severe anæmia, thyrotoxicosis, and abnormal tachycardia—in which failure may involve the heart as a whole, the syndromes of primary left and primary right heart-failure are generally accepted nowadays as applicable to the majority of cases.

The factors responsible for left heart-failure are cardiac enlargement and myocardial incompetence resulting from such disorders as hypertension and aortic valve disease. In its early stages the condition is associated with congestion in the pulmonary circuit, the failing left ventricle being incapable of maintaining its output without a considerable rise in the filling pressure in the pulmonary veins (McMichael 1938). Though for a time it is compensatory, sooner or later venous congestion in the pulmonary circuit becomes a handicap; it is to blame for the diminished vital capacity which characterises the early stages of left heart-failure and it is a major factor in such developments as acute paroxysmal dyspnœa and pulmonary œdema which may supervene later.

Acute paroxysmal dyspnœa is usually precipitated by an emotional disturbance or by a physical effort, its course being aggravated by spasms of violent coughing and general restlessness which accelerate the venous return to the right heart, incidentally increasing the pulmonary congestion already existing. Wheezing, of varying degree, usually intensifies the urgency of acute attacks of paroxysmal dyspnœa; these attacks may be allergic in origin, the loss of cardiac reserve and the circulatory discrepancies incidental to them being the non-specific factors which initiate the bronchial spasm.

In cardiac cases, *acute pulmonary œdema* signifies an extreme degree of left ventricular failure, and its pathological background includes the interaction of three distinct processes: (1) a sudden exacerbation of pulmonary congestion; (2) an increased permeability of the lung capillaries due partly to anoxia and partly to nervous reflexes; and (3) an acute reflex dilatation of the pulmonary vessels.

The physical signs of an acute effusion of fluid into the lungs are characteristic, as also are the radiological appearances, which include patchy areas of shadowing, chiefly central in site, with the apices and bases remaining relatively clear. Pulmonary œdema is always a grave complication in patients with cardiac failure, and particularly in those with grossly enlarged hearts whose cardiograms indicate myocardial dysfunction and who during their attacks, present urgent symptoms of shock or such grave signs as triple rhythm, pulsus alternans, or a diminishing range of pulse-pressure. The serious significance of attacks of pulmonary œdema in the prognosis of patients suffering from left heart-failure is generally recognised; they express in conclusive form the unbalanced action of the two ventricles, and they frequently prelude the development of right heart-failure, after which they tend, as a rule, to subside entirely.

RIGHT HEART-FAILURE

Right heart-failure is usually secondary to high-grade decompensation of the left ventricle consequent on such affections as hypertension and valvular disease; other ætiological factors include pulmonary hypertension, diseases of the pulmonary vascular system (primary endarteritis and thrombosis of the smaller vessels (Rosenthal 1930)), chronic pulmonary diseases (emphysema, pneumoconiosis, and pulmonary fibrosis), and kyphoscoliosis.

The physical signs of right heart-failure are usually clear: they include engorgement of the systemic venous system with jugular stasis and pulsation in the upright or the semi-upright position, enlargement of the liver, œdema, ascites, and possibly also hydrothorax (usually right) if, as was noted by Bedford and Lovibond (1941), the condition is complicated by pulmonary engorgement.

Accurate assessment of the enlargement of the right ventricle is essentially a radiological problem, and an electrocardiogram is equally valuable in that it furnishes evidence of the ventricular hypertrophy and of any such myocardial dysfunction as may be associated therewith.

The term *idiopathic* or *essential pulmonary hypertension* was applied in 1940 by Terence East to a group of cases whose clinical course was typical of pure and intractable right ventricular failure. He noted particularly their relative freedom from breathlessness, and he excluded syphilis and pulmonary disease, as well as valvular defects, both congenital and acquired. The post-mortem findings always included enlargement of the right ventricle, with massive hypertrophy of its walls and thick trabeculæ, dilatation of the pulmonary artery, and a left auricle of normal capacity and thickness. In one case there were small atheromatous patches at the bifurcation of the pulmonary artery, and small ones in the first main branches; also the muscle coats of the arterioles were perhaps slightly hypertrophied. In another case there was slight atheroma of the pulmonary artery, the muscular coats of the small arterioles were perhaps slightly thickened and a few of the arterioles were partly obliterated by proliferation of the intima. No satisfactory cause for the right ventricular hypertrophy being revealed at necropsy, East suggested the existence of a primary pulmonary hypertension, the changes (both atheromatous and obliterative) in the pulmonary arteries and arterioles being secondary thereto.

A case somewhat similar to these is recorded by Armstrong (1940).

> The patient, a woman of 73, suffered from long-continued (42 years) right ventricular failure, the striking feature of her symptom-complex being a relative absence of breathlessness in the presence of a very severe degree of systemic venous engorgement. At necropsy the right ventricle was found to be extremely hypertrophied, and microscopy showed severe atheroma in the pulmonary artery and its branches, the pulmonary arterioles presenting no abnormality and no obstruction.

Judging by these findings, which excluded any evidence of obstructive disease in the pulmonary circuit, Armstrong thought that the atheroma in the pulmonary vessels was of hypertensive origin, and that it was not possible to decide whether the right ventricular hypertrophy was the cause or the result of the pulmonary hypertension.

Barrett and Cole (1946) published the clinical notes and the post-mortem record of a patient with pulmonary vascular sclerosis who died of right ventricular failure within four months of the first symptom. The morbid changes in the lungs included disintegration of the alveolar walls and destruction of the capillary bed, also widespread and severe disease of the larger pulmonary arteries and arterioles. Barrett and Cole held that these abnormalities had increased the resistance in the pulmonary circuit and were primarily responsible for the hypertrophy and the dilatation of the chambers of the right heart. They were of opinion that all the vascular lesions were probably the result of pulmonary hypertension, and that the circulatory impairment caused by the vascular lesions was responsible for the disintegration of the alveolar walls. On both clinical and pathological grounds, they believed the case could be regarded as one of malignant pulmonary hypertension; a rise of pulmonary blood-pressure had initiated malignant sclerosis of the pulmonary arterioles which had then exaggerated the pulmonary hypertension, thus setting up a vicious circle.

It is generally agreed that *chronic lung disease* usually imposes an increased demand on the right heart, in the explanation of which a variety of factors have been considered. The ill effects induced by destruction of the pulmonary capillary bed have been discounted by McMichael (1947), who found that, after obliteration of half the vascular bed in the lungs by ligature of the left pulmonary artery, the pulmonary arterial pressure was unchanged. He further noted that the pulmonary blood-pressure, as determined by cardiac catheterisation, was elevated in emphysema far less than in mitral stenosis. Other factors he emphasised are the high cardiac output characteristic of emphysema except in its terminal phases, and the reduced arterial oxygen tension—probably the result of poor ventilation and vasoconstriction—which in pulmonary heart-failure may fall to as low a figure as 33%.

Parkinson and Hoyle (1937) studied emphysema in its relation to failure of the right heart. They concluded that gross enlargement of the right ventricle was uncommon even with severe chronic hypertrophic emphysema. They regarded the cardiac signs and symptoms which often develop in emphysema patients as expressing systemic hypertension rather than any specific cardiac condition for which the emphysema could be responsible. Further, they concluded that, in the absence of cardiovascular disease, emphysema is unlikely to cause right heart-failure, except in the terminal stage.

Bernheim (1910) recognised that right ventricular failure might develop in patients suffering from compensated *lesions affecting the left heart*: the interventricular septum, bulging into the cavity of the right ventricle, materially obstructing its filling capacity. This syndrome is amply described by the term "right ventricular stenosis," and in typical cases it can nowadays be recognised clinically with fair confidence.

East and Bain (1949), discussing cases in which the underlying lesion was either hypertension or aortic stenosis, listed the following diagnostic criteria:

1. Gross congestive failure, without embarrassment of the pulmonary circulation, in the presence of a predominantly left-sided lesion.
2. Radiological confirmation of left ventricular hypertrophy, dilatation of the right auricle, and clear lung fields.
3. A grossly thickened interventricular septum encroaching on the cavity of the right ventricle.
4. Dryness of the lungs and their freedom from engorgement and œdema as proved by their normal weight at autopsy.

They emphasised the clinical similarity of right ventricular stenosis and tricuspid stenosis, in both of which there is conspicuous systemic engorgement but no pulmonary congestion. They suggested that intracardiac catheterisation might be of value in the clinical assessment of right ventricular stenosis and that the peculiar shape of the right ventricular cavity might be displayed by angiocardiography.

Bedford et al. (1946) reviewed right heart-failure secondary to *bilharzial pulmonary endarteritis* and described a typical case as follows:

> A man, aged 34, was admitted to hospital with 3 years' history of breathlessness on exertion, cough with slight expectoration, precordial pain, and hæmaturia. There was no clubbing of the fingers, and no cyanosis, œdema, or jugular stasis. Pulsation was visible and palpable in the 1st and 2nd left interspaces and the pulmonary second sound was much accentuated. The chest was emphysematous in shape but there were no added sounds in the lungs. Radioscopy showed an aneurysmal swelling in the region of the main pulmonary trunk, and the right pulmonary artery in the hilum formed a swelling of aneurysmal proportions.
>
> Three weeks after admission, the patient became urgently ill. He complained of pain over the liver, the cervical veins became engorged, there was marked cyanosis, gallop rhythm was audible at the apex region, and he died a few days later. The necropsy findings included gross dilatation, thickening, and atheroma of the pulmonary trunk, with aneurysmal swellings and advanced ulcerated atheroma of both its main branches, each of which was almost occluded by antemortem thrombus. The aorta was hypoplastic, and the right auricle and ventricle were considerably hypertrophied, their cavities being dilated to about three times their normal capacity. Sections of both lungs were examined. The alveoli were normal except for slight venous congestion and extravasations of red cells. The pulmonary arterioles were much thickened

and showed obliterative endarteritis. There were numerous angiomatoids, of both the capillary and the cavernous types, typical of bilharzial pulmonary arteritis. Bilharzial ova were seen in relation to some of the arterioles. Sections from the trunk and two main branches of the pulmonary artery showed atheroma and calcification. The adventitia showed thickened vasa vasorum with perivascular infiltration by lymphocytes and plasma-cells. In the main branches there was organised thrombus of moderate age.

The authors were of opinion that, as compared with other forms of chronic cor pulmonale, the variety due to bilharzial disease affects younger subjects, and that as a general rule the patients are relatively free from cyanosis except in the final stages of the disease. The absence of cyanosis was, they suggested, due to the fact that in bilharzial lung infection the alveolar and the capillary structures remain intact and the pulmonary lesions are chiefly confined to the arterioles, so accounting for the pulmonary hypertension and the symptoms of right heart-failure. They noted too that in bilharzial disease radiography of the chest seldom shows changes in the lung fields other than vascular dilatation. They commented on the close similarity of the radiological appearances of the heart in atrioseptal defect and in cor pulmonale of bilharzial origin, both of which show gross dilatation of the pulmonary trunk and hilar branches aneurysmal in size.

Ischæmic Heart-failure

In the large majority of cases of ischæmic heart-disease the underlying pathology of failure is atherosclerosis of the coronary vessels. In a relatively small proportion the condition is due to implication of the coronary arteries in syphilitic aortitis, to anæmia, to aortic stenosis, to hypotension, to bradycardia, or to paroxysmal tachycardia.

The symptomatology of atherosclerotic heart-disease can best be illustrated by an analysis of case-histories, and I have selected a group of twelve patients for consideration here. It comprises nine men and three women, of ages ranging from 51 to 76, the average age of the women being 66, that of the men 60.

In all the patients the initial symptom was anginal pain; five complained in addition of effort breathlessness and it was noteworthy that, before the onset of these symptoms, most of the patients had regarded their general health and exercise tolerance as singularly good for their age.

The personal history of the patients was regarded as of fundamental importance in arriving at a diagnosis; for, though the physical and the cardiographic examinations revealed a variety of inconstant abnormalities, these could not be considered specific for ischæmic heart-disease.

Briefly summarised, the after-history of the twelve patients was as follows. Four died from cardiac failure following acute myocardial infarction, which occurred 2–12 years from the onset of cardiac symptoms. Five patients were alive 1–5 years after the onset, all living restricted but quietly active lives with comparative freedom from symptoms. Three patients, whose histories ranged from 1 year to 18 months, are still subject to recurrences of anginal pain both with exertion and at rest, these attacks being so protracted and severe as to simulate the syndrome of myocardial infarction.

The explanation of such attacks has been reviewed by East and Oram (1948), who analysed three hundred and sixty-seven cases in which the clinical picture and the cardiographic evidence had been thought indicative of cardiac infarction. In twenty-eight, the cardiograms, after intervals varying from days to weeks or months, reverted to a normal pattern and remained normal. In most of these the original curves had suggested an anterior distribution; the Q waves were absent or insignificant and, with two exceptions, there was no material displacement of the RS-T segments. East and Oram suggested that cardiac pain, with cardiographic discrepancies somewhat similar to those of infarction might in fact be due to local pathological changes other than infarction. Their final conclusion was that the cardiographic abnormalities in their cases were due to myocardial ischæmia caused by spasm of the coronary vessels. They quoted the experimental results of Bayley and La Due (1944) who stated that "the electrical phenomena resulting from occlusion of the anterior descending branch of the left coronary artery were entirely independent of demonstrable pathological changes and that ischæmic injury changes, though frequently associated with infarction in man, are not to be regarded as necessarily diagnostic of infarction."

TERMINATION

In the first of my four fatal cases the patient was a man aged 59, with 2 years' history of effort angina.

He woke with severe substernal pain which radiated to both arms and to the lower jaw; there was dyspnœa, restlessness, and a considerable degree of collapse, unrelieved by nitrite medication. When I saw him on the 2nd day of his illness the presenting signs were those of vasomotor collapse, with hypotension (80/60 mm. Hg), tachycardia, and triple rhythm, and the cardiograms were confirmatory of an anteroseptal cardiac infarct. The condition deteriorated rapidly, and, in addition to increasing left ventricular failure, a harsh and prolonged systolic murmur developed, of maximum intensity in the 4th space at the left sternal margin. This murmur, accompanied by a systolic thrill, persisted from the 7th to the 10th day when the man died suddenly, presumably of ventricular fibrillation.

Although necropsy was refused in this case, the clinical evidence appeared to warrant the diagnosis of a perforated septal infarct.

The second case was that of a woman, aged 60, in whom the initial symptoms included a prolonged syncopal attack, severe shock, and acute pain which continued for 36 hours.

The patient rallied gradually, but on the 6th day of her illness the pain recurred, with bradycardia, feelings of faintness, and urgent breathlessness. The cardiogram showed sinus bradycardia, rate 42, with a normal P-R interval and abnormalities in the ventricular complexes of leads II, III, and V_7, typical of a posterior myocardial infarct. Next day, after a violent attack of vomiting, the patient collapsed and died.

Cookson (1942) has reported fifteen cases of cardiac infarction in which syncopal symptoms were prominent at the onset or during the course of the illness. In ten of them syncope occurred at the onset, the presenting symptoms being peripheral circulatory failure, often combined with a slow heart-rate, or with abnormal rhythms of supraventricular origin, and rarely with ventricular tachycardia. Of these ten patients, six were dead within four months, and Cookson suggested that the principal cause of the syncopal seizures was a nervous reflex leading to vasomotor depression and to vagal stimulation with consequent bradycardia, subsidiary effects being the impaired efficiency of systole resulting from the inactivity of the infarcted area of myocardium and direct ischæmic effects on the auricles causing bradycardia and abnormal rhythms. In the other five patients, syncope or fits occurred after the onset of cardiac infarction; two had syncope and three had Stokes-Adams attacks; abnormal rhythms were recorded in four, and all the patients died within 29 days of the onset of their illness.

The two remaining patients in my group who died of heart-failure following acute myocardial infarction were men aged 71 and 58.

The first had been under treatment 10 years previously for cardiac failure of indeterminate origin, there being no history of rheumatic fever. The heart was considerably enlarged but the blood-pressure was within normal limi such myocardial dysfunction as may be associated therewith.

The term *idiopathic* or *essential pulmonary hypertension* was applied in 1940 by Terence East to a group of cases whose clinical course was typical of pure and intractable right ventricular failure. He noted particularly their relative freedom from breathlessness, and he excluded syphilis and pulmonary disease, as well as valvular defects, both congenital and acquired. The post-mortem findings always included enlargement of the right ventricle, with massive hypertrophy of its walls and thick trabeculæ, dilatation of the pulmonary artery, and a left auricle of normal capacity and thickness. In one case there were small atheromatous patches at the bifurcation of the pulmonary artery, and small ones in the first main branches; also the muscle coats of the arterioles were perhaps slightly hypertrophied. In another case there was slight atheroma of the pulmonary artery, the muscular coats of the small arterioles were perhaps slightly thickened and a few of the arterioles were partly obliterated by proliferation of the intima. No satisfactory cause for the right ventricular hypertrophy being revealed at necropsy, East suggested the existence of a primary pulmonary hypertension, the changes (both atheromatous and obliterative) in the pulmonary arteries and arterioles being secondary thereto.

A case somewhat similar to these is recorded by Armstrong (1940).

> The patient, a woman of 73, suffered from long-continued (42 years) right ventricular failure, the striking feature of her symptom-complex being a relative absence of breathlessness in the presence of a very severe degree of systemic venous engorgement. At necropsy the right ventricle was found to be extremely hypertrophied, and microscopy showed severe atheroma in the pulmonary artery and its branches, the pulmonary arterioles presenting no abnormality and no obstruction.

Judging by these findings, which excluded any evidence of obstructive disease in the pulmonary circuit, Armstrong thought that the atheroma in the pulmonary vessels was of hypertensive origin, and that it was not possible to decide whether the right ventricular hypertrophy was the cause or the result of the pulmonary hypertension.

Barrett and Cole (1946) published the clinical notes and the post-mortem record of a patient with pulmonary vascular sclerosis who died of right ventricular failure within four months of the first symptom. The morbid changes in the lungs included disintegration of the alveolar walls and destruction of the capillary bed, also widespread and severe disease of the larger pulmonary arteries and arterioles. Barrett and Cole held that these abnormalities had increased the resistance in the pulmonary circuit and were primarily responsible for the hypertrophy and the dilatation of the chambers of the right heart. They were of opinion that all the vascular lesions were probably the result of pulmonary hypertension, and that the circulatory impairment caused by the vascular lesions was responsible for the disintegration of the alveolar walls. On both clinical and pathological grounds, they believed the case could be regarded as one of malignant pulmonary hypertension; a rise of pulmonary blood-pressure had initiated malignant sclerosis of the pulmonary arterioles which had then exaggerated the pulmonary hypertension, thus setting up a vicious circle.

It is generally agreed that *chronic lung disease* usually imposes an increased demand on the right heart, in the explanation of which a variety of factors have been considered. The ill effects induced by destruction of the pulmonary capillary bed have been discounted by McMichael (1947), who found that, after obliteration of half the vascular bed in the lungs by ligature of the left pulmonary artery, the pulmonary arterial pressure was unchanged. He further noted that the pulmonary blood-pressure, as determined by cardiac catheterisation, was elevated in emphysema far less than in mitral stenosis. Other factors he emphasised are the high cardiac output characteristic of emphysema except in its terminal phases, and the reduced arterial oxygen tension—probably the result of poor ventilation and vasoconstriction—which in pulmonary heart-failure may fall to as low a figure as 33%.

Parkinson and Hoyle (1937) studied emphysema in its *relation to failure of the right heart.* They concluded that gross enlargement of the right ventricle was uncommon even with severe chronic hypertrophic emphysema. They regarded the cardiac signs and symptoms which often develop in emphysema patients as expressing systemic hypertension rather than any specific cardiac condition for which the emphysema could be responsible. Further, they concluded that, in the absence of cardiovascular disease, emphysema is unlikely to cause right heart-failure, except in the terminal stage.

Bernheim (1910) recognised that right ventricular *failure might develop in patients suffering from compensated lesions affecting the left heart*: the interventricular septum, bulging into the cavity of the right ventricle, materially obstructing its filling capacity. This syndrome is amply described by the term "right ventricular stenosis," and in typical cases it can nowadays be recognised clinically with fair confidence.

East and Bain (1949), discussing cases in which the underlying lesion was either hypertension or aortic stenosis, listed the following diagnostic criteria:

1. Gross congestive failure, without embarrassment of the pulmonary circulation, in the presence of a predominantly left-sided lesion.
2. Radiological confirmation of left ventricular hypertrophy, dilatation of the right auricle, and clear lung fields.
3. A grossly thickened interventricular septum encroaching on the cavity of the right ventricle.
4. Dryness of the lungs and their freedom from engorgement and œdema as proved by their normal weight at autopsy.

They emphasised the clinical similarity of right ventricular stenosis and tricuspid stenosis, in both of which there is conspicuous systemic engorgement but no pulmonary congestion. They suggested that intracardiac catheterisation might be of value in the clinical assessment of right ventricular stenosis and that the peculiar shape of the right ventricular cavity might be displayed by angiocardiography.

Bedford et al. (1946) reviewed right heart-failure secondary to *bilharzial pulmonary endarteritis* and described a typical case as follows:

> A man, aged 34, was admitted to hospital with 3 years' history of breathlessness on exertion, cough with slight expectoration, precordial pain, and hæmaturia. There was no clubbing of the fingers, and no cyanosis, œdema, or jugular stasis. Pulsation was visible and palpable in the 1st and 2nd left interspaces and the pulmonary second sound was much accentuated. The chest was emphysematous in shape but there were no added sounds in the lungs. Radioscopy showed an aneurysmal swelling in the region of the main pulmonary trunk, and the right pulmonary artery in the hilum formed a swelling of aneurysmal proportions.
>
> Three weeks after admission, the patient became urgently ill. He complained of pain over the liver, the cervical veins became engorged, there was marked cyanosis, gallop rhythm was audible at the apex region, and he died a few days later. The necropsy findings included gross dilatation, thickening, and atheroma of the pulmonary trunk, with aneurysmal swellings and advanced ulcerated atheroma of both its main branches, each of which was almost occluded by antemortem thrombus. The aorta was hypoplastic, and the right auricle and ventricle were considerably hypertrophied, their cavities being dilated to about three times their normal capacity. Sections of both lungs were examined. The alveoli were normal except for slight venous congestion and extravasations of red cells. The pulmonary arterioles were much thickened

and showed obliterative endarteritis. There were numerous angiomatoids, of both the capillary and the cavernous types, typical of bilharzial pulmonary arteritis. Bilharzial ova were seen in relation to some of the arterioles. Sections from the trunk and two main branches of the pulmonary artery showed atheroma and calcification. The adventitia showed thickened vasa vasorum with perivascular infiltration by lymphocytes and plasma-cells. In the main branches there was organised thrombus of moderate age.

The authors were of opinion that, as compared with other forms of chronic cor pulmonale, the variety due to bilharzial disease affects younger subjects, and that as a general rule the patients are relatively free from cyanosis except in the final stages of the disease. The absence of cyanosis was, they suggested, due to the fact that in bilharzial lung infection the alveolar and the capillary structures remain intact and the pulmonary lesions are chiefly confined to the arterioles, so accounting for the pulmonary hypertension and the symptoms of right heart-failure. They noted too that in bilharzial disease radiography of the chest seldom shows changes in the lung fields other than vascular dilatation. They commented on the close similarity of the radiological appearances of the heart in atrioseptal defect and in cor pulmonale of bilharzial origin, both of which show gross dilatation of the pulmonary trunk and hilar branches aneurysmal in size.

Ischæmic Heart-failure

In the large majority of cases of ischæmic heart-disease the underlying pathology of failure is atherosclerosis of the coronary vessels. In a relatively small proportion the condition is due to implication of the coronary arteries in syphilitic aortitis, to anæmia, to aortic stenosis, to hypotension, to bradycardia, or to paroxysmal tachycardia.

The symptomatology of atherosclerotic heart-disease can best be illustrated by an analysis of case-histories, and I have selected a group of twelve patients for consideration here. It comprises nine men and three women, of ages ranging from 51 to 76, the average age of the women being 66, that of the men 60.

In all the patients the initial symptom was anginal pain; five complained in addition of effort breathlessness and it was noteworthy that, before the onset of these symptoms, most of the patients had regarded their general health and exercise tolerance as singularly good for their age.

Five patients were alive 1–5 years after the onset, all living restricted but quietly active lives with comparative freedom from symptoms. Three patients, whose histories ranged from 1 year to 18 months, are still subject to recurrences of anginal pain both with exertion and at rest, these attacks being so protracted and severe as to simulate the syndrome of myocardial infarction.

The explanation of such attacks has been reviewed by East and Oram (1948), who analysed three hundred and sixty-seven cases in which the clinical picture and the cardiographic evidence had been thought indicative of cardiac infarction. In twenty-eight, the cardiograms, after intervals varying from days to weeks or months, reverted to a normal pattern and remained normal. In most of these the original curves had suggested an anterior distribution; the Q waves were absent or insignificant and, with two exceptions, there was no material displacement of the RS-T segments. East and Oram suggested that cardiac pain, with cardiographic discrepancies somewhat similar to those of infarction might in fact be due to local pathological changes other than infarction. Their final conclusion was that the cardiographic abnormalities in their cases were due to myocardial ischæmia caused by spasm of the coronary vessels. They quoted the experimental results of Bayley and La Due (1944) who stated that "the electrical phenomena resulting from occlusion of the anterior descending branch of the left coronary artery were entirely independent of demonstrable pathological changes and that ischæmic injury changes, though frequently associated with infarction in man, are not to be regarded as necessarily diagnostic of infarction."

TERMINATION

In the first of my four fatal cases the patient was a man aged 59, with 2 years' history of effort angina.

He woke with severe substernal pain which radiated to both arms and to the lower jaw; there was dyspnœa, restlessness, and a considerable degree of collapse, unrelieved by nitrite medication. When I saw him on the 2nd day of his illness the presenting signs were those of vasomotor collapse, with hypotension (80/60 mm. Hg), tachycardia, and triple rhythm, and the cardiograms were confirmatory of an antero-septal cardiac infarct. The condition deteriorated rapidly, and, in addition to increasing left ventricular failure, a harsh and prolonged systolic murmur developed, of maximum intensity in the 4th space at the left sternal margin. This murmur, accompanied by a systolic thrill, persisted from the 7th to the 10th day when the man died suddenly, presumably of ventricular fibrillation.

Although necropsy was refused in this case, the clinical evidence appeared to warrant the diagnosis of a perforated septal infarct.

The second case was that of a woman, aged 60, in whom the initial symptoms included a prolonged syncopal attack, severe shock, and acute pain which continued for 36 hours.

The patient rallied gradually, but on the 6th day of her illness the pain recurred, with bradycardia, feelings of faintness, and urgent breathlessness. The cardiogram showed sinus bradycardia, rate 42, with a normal P-R interval and abnormalities in the ventricular complexes of leads II, III, and V_7 typical of a posterior myocardial infarct. Next day, after a violent attack of vomiting, the patient collapsed and died.

Cookson (1942) has reported fifteen cases of cardiac infarction in which syncopal symptoms were prominent at the onset or during the course of the illness. In ten of them syncope occurred at the onset, the presenting symptoms being peripheral circulatory failure, often combined with a slow heart-rate, or with abnormal rhythms of supraventricular origin, and rarely with ventricular tachycardia. Of these ten patients, six were dead within four months, and Cookson suggested that the principal cause of the syncopal seizures was a nervous reflex leading to vasomotor depression and to vagal stimulation with consequent bradycardia, subsidiary effects being the impaired efficiency of systole resulting from the inactivity of the infarcted area of myocardium and direct ischæmic effects on the auricles causing bradycardia and abnormal rhythms. In the other five patients, syncope or fits occurred after the onset of cardiac infarction; two had syncope and three had Stokes-Adams attacks; abnormal rhythms were recorded in four, and all the patients died within 29 days of the onset of their illness.

The two remaining patients in my group who died of heart-failure following acute myocardial infarction were men aged 71 and 58.

The first had been under treatment 10 years previously for cardiac failure of indeterminate origin, there being no history of rheumatic fever. The heart was considerably enlarged but the blood-pressure was within normal limi and there were no signs of valvular or vascular disease. He made an uncomplicated recovery from the immediate effects of his acute myocardial infarction; but signs of congestive heart-failure became increasingly evident early in convalescence, his response to treatment was disappointing, and he died in his sleep during the 12th week of his illness.

The second patient had been treated for high blood-pressure in early adult life; his heart was enlarged, and the radiological appearances were typical of left ventricular hypertrophy with an elongated and tortuous aorta. The cardiogram, besides locating a posterior basal infarct, showed changes in the unipolar chest records which confirmed the left ventricular hypertrophy. The man's condition deteriorated rapidly; he developed increasing pulmonary congestion; and he died suddenly on the 6th day.

RADIOGRAPHY

Recent work by Harrison and Paul Wood (1949) shows the value of radiography in the pathological study of ischæmic heart-disease. On the clinical side their investigations demonstrated a 2 to 1 sex-distribution in favour of males and a later age for females. In the early stages anginal pain was usually, and dyspnœa rarely, the outstanding symptom. There was an impalpable cardiac impulse and a normal rhythm, and, in the absence of hypertension or heart-failure, the size of the heart was normal. In the presence of failure there was cardiac enlargement, the degree of the latter being proportionate to the duration of the former. Renal efficiency was usually within normal limits; fundi and valves were normal; blood-pressure was moderately raised. Sooner or later myocardial infarction occurs, after which, except in the small proportion of patients whose compensation is for a time restored, the disease progresses by stages from left ventricular failure to systemic congestion and sudden cardiac death.

For their radiographic post-mortem investigations Harrison and Wood injected the coronary arteries with radio-opaque jelly at the known diastolic pressure of the patients, after which they recorded stereoscopic skiagrams by the standard technique. The hearts were then dehydrated in alcohol and cleared in a bath of methyl salicylate, the coronary vessels being thus clearly defined in the relatively transparent tissue. The skiagrams and the cleared specimens always showed severe narrowing or occlusion of the coronary arteries, and usually both. In eight of the fifteen cases the whole coronary tree was affected, the major arteries being narrowed and irregular, often with deposits of calcium in their walls. In the other seven cases arterial narrowing was limited to one vessel, while the rest of the coronary tree was relatively normal. In thirteen of the cases there were fourteen healed infarcts, the large majority involving the left ventricle. Anastomotic vessels in relation to the distal segments of the occluded vessels were visible in all the cases and these sufficed to permit their retrograde filling. In most of the skiagrams, though the lumen of the majority of the vessels was narrowed or irregular, some segments looked normal in calibre; yet these segments showed severe atheroma microscopically. In explanation of this apparent discrepancy, the investigators argued that coronary atheroma is compatible with a normal lumen, and they noted that it was impossible, on the skiagraphic evidence alone, to decide whether a focus of narrowing was due to atheroma or to a recanalised thrombus.

A further significant finding in Harrison and Wood's series was the development in the myocardium of minute foci of necrosis leading to fibrosis. These lesions, just visible macroscopically, were observed in every stage of their development, and it was seen that they were exactly like ordinary infarcts on a minute scale. It was suggested that they should be regarded as such, and that the term ischæmic fibrosis should imply the existence of such lesions.

(To be concluded)

PERFORATED PEPTIC ULCER

AN ASSESSMENT OF THE VALUE OF NONOPERATIVE TREATMENT

B. McN. Truscott

SURGEON

J. F. R. Withycombe
M.A., M.B. Camb., F.R.C.S.
RESIDENT SURGICAL OFFICER

ADDENBROOKE'S HOSPITAL, CAMBRIDGE

The stimulating papers by Taylor (1946) and Visick (1946) on the conservative treatment of perforated peptic ulcer, led us to treat cases in this way and to compare the results with those obtained in the same period in cases treated by the usual operative method. The number of cases is too small for our findings to be statistically significant, but the trial has given us a fair experience of the conservative method and the impressions we have gained seem worth recording.

MATERIAL

The cases treated were all emergency admissions to Addenbrooke's Hospital between January, 1947, and February, 1949. The patients treated conservatively were admitted on the "take-in days" of one of us. Cases admitted on the take-in days of our surgical colleagues were operated on and form the series for comparison; we are indebted to these colleagues for permission to report their results.

The selection was therefore based simply on which day of the week the patient was admitted to hospital, with the exception of 2 patients whose ulcers perforated in a medical ward and whom we were asked to see by their physician. We were prepared to reject any case that we considered unsuitable for conservative treatment for the reasons laid down by Taylor (1946)—i.e., a recent heavy meal, pyloric stenosis, gross flooding of the peritoneal cavity, or established peritonitis—but in fact no such rejection had to be made.

We feel that the nature of the country from which the cases were drawn is important. Some came from the immediate neighbourhood of Cambridge, but others came from the remoter areas of rural East Anglia and were subject to the delays and long journeys inevitable in such an area. This fact should be borne in mind when comparing the results as a whole with those of a series drawn from an entirely urban area.

DIAGNOSIS

A criticism which may be made in considering the results of conservative treatment is that the diagnosis of perforated ulcer may be uncertain without the confirmation of a laparotomy. Only those cases, therefore, in which the clinical diagnosis was firm have been included. Each patient was seen on admission by one, and if possible by both, of us. If anything, the diagnosis received more careful deliberation than usual because the moral support of an early operation was to be lacking. Where the patient's condition permitted, an attempt was made to support the diagnosis radiologically by demonstrating gas under the diaphragm. In many instances a barium meal during convalescence showed an ulcer or the scar of a healed ulcer. One man, who refused to attend for a barium meal because he felt so well, died some time later after a massive hæmatemesis from a large gastric ulcer, and at necropsy there was evidence of a relatively recent perforation. In several cases which were subsequently treated by gastrectomy evidence of the healed perforation was found at the operation. Therefore, though the possibility of error is admitted, the number of misdiagnoses is likely, at the worst, to have been very small. We must confess to one case which we both confidently diagnosed as a perforation but which eventually proved to be cholecystitis.

TREATMENT AND RESULTS

The details of the conservative treatment we adopted are similar to those described by Taylor (1946), with one minor modification—we did not use the wide-bore stomach-tube as a routine for preliminary emptying of the stomach. In cases where the history suggested that the stomach was empty at the time of perforation we were content to use a Ryle's tube throughout.

The results in the two groups of patients were as follows:

	All cases admitted	*Conservative treatment*	*Operative treatment*
No. of patients	59	20	37
No. of deaths	7*	3	2
Fatality-rate	11·8%	15%	5·4%

* Including 2 cases admitted moribund and unfit for any form of treatment.

The case-histories of the 5 fatal cases (excluding the 2 patients admitted moribund) may be summarised as follows.

Conservative Method

Case 1.—Man, aged 63, admitted twelve hours after perforation. Progress satisfactory for six days when symptoms developed suggestive of delirium tremens. Died ten days after admission. Necropsy showed sealed perforation; small collection of pus in subphrenic space.

Case 2.—Man, aged 60, admitted twelve hours after perforation. Progress satisfactory for forty-eight hours but then deteriorated with cyanosis. Died three days after admission. Necropsy showed perforation of duodenum 1 in. in diameter; œdema of lungs.

Case 3.—Man, aged 56, admitted seven hours after perforation. Collapsed twelve hours after start of treatment. Condition steadily deteriorated. Died fifty-six hours after admission. Necropsy showed perforated duodenal ulcer with fibropurulent peritonitis in neighbourhood of perforation, and early bronchopneumonia.

Operative Method

Case 4.—Man, aged 50, admitted fifteen hours after perforation. Collapsed during induction with thiopentone. Heart and respiration restarted with cardiac massage. Died an hour later.

Case 5.—Man, aged 39, admitted ten hours after perforation. Perforated gastric ulcer sutured under general anæsthesia. Condition was poor on admission, with cyanosis suggestive of peripheral vascular failure. Steady deterioration. Died three days after admission.

In case 1 the man was well on the way to recovery when he developed mental symptoms. Although he had a small collection of pus under the diaphragm it was not sufficient to cause death. The delirium tremens seems to have been the reason for the failure of treatment, but in our opinion this does not justify exclusion of the case from the fatality-rate.

We cannot say why cases 2 and 3 did not respond to treatment. Both were men in apparently good condition who, judging by our experience of the previous cases, should have recovered. In case 2 the necropsy revealed some œdema of the lungs, but the fluid balance was carefully controlled and we do not think his circulation was overloaded.

DISCUSSION

As a result of this experience we have come to the conclusion that the conservative method is not so good, except in special circumstances, as immediate operation, though it has a definite place in the treatment of perforated peptic ulcers. Our reasons for this conclusion are not easy to define. We did not come to it suddenly, as a result of studying figures. Rather did it arise out of a vague sense of uneasiness, not obviously justified by a catastrophe, which rapidly changed into real apprehension when two cases in quick succession failed to respond.

The *advantages* of the method are as follows:

(1) Avoidance of the physical and mental upsets of an operation.

(2) The relative comfort of the patient. On 3 occasions we used it in patients who had perforated before and been treated by operation. Without exception they found their convalescence more comfortable after conservative treatment and were enthusiastic supporters of the method.

(3) The relative freedom from intra-abdominal adhesions. Several cases have had a gastrectomy some months later, and we have been impressed by the few adhesions present compared to the usual finding after operative treatment. We were particularly impressed by this observation because it was contrary to our expectations.

(4) When the patient is a bad operative risk—in the elderly, or those with concomitant medical disabilities such as respiratory or cardiac disease—the conservative method avoids the additional strain of an anæsthetic. In the occasional case where the perforation leads to a rapid deterioration in the patient's general condition, and the response to resuscitation is slow, an anæsthetic is always hazardous, and the delay before an operation can be undertaken may be serious. Conservative treatment can be started immediately and go hand in hand with resuscitation.

(5) When medical conditions mimic a perforation. Conservative treatment is particularly valuable when it is not certain whether the patient has a perforation or a medical condition such as coronary thrombosis or diaphragmatic pleurisy. An anæsthetic, which may be fatal, is avoided.

(6) When the signs of perforation are indefinite. Where the signs suggest a severe flare-up of an old chronic ulcer, or perhaps a small leakage, one hesitates to delay operation and await developments if no other treatment is available. With the conservative method these anxieties are absent, for it is particularly successful in this type of case, and the treatment can be applied without the risk of inflicting an unnecessary operation on the patient.

(7) The average stay in hospital before transfer to a convalescent home was 12 days in the cases treated conservatively and 17 days in those treated by operation. On the whole, therefore, the conservative method was quicker than the operative. There were not enough cases to provide any statistical evidence on the incidence of complications with the two methods of treatment. Such figures as we were able to collect support our impression that there are fewer complications with conservative treatment. A point of interest is that two cases out of the twenty treated conservatively had hæmatemesis during treatment, a very rare complication when the ulcer is sutured. On the other hand, one patient, whose ulcer perforated while he was in hospital being treated for a severe melæna and was still bleeding at the time of perforation, responded well to conservative treatment and recovered without incident.

The *disadvantages* of the conservative method are:

(1) The fatality-rate for conservative treatment was 15% and for the operative method 5·4%, but the series was too small for this difference to be more than an indication.

(2) The possibility of mistaken diagnosis is the gravest objection to conservative treatment. There must be few surgeons who have not confidently diagnosed a perforated ulcer and found at laparotomy some other condition, particularly an acute appendicitis. The attempt to treat such a case by the conservative method might be disastrous. By good fortune such a mistake did not happen to us, but the possibility gave us constant anxiety.

(3) When a case does badly under conservative treatment one gets an unhappy feeling that all that might have been done has not been done. If operative treatment fails one does at least feel that all possible aid has been given. There is probably no logical reason why a fatality after operation is easier to bear than a fatality after conservative treatment, but the fact remains that this was one of the main reasons for our uneasiness.

CONCLUSIONS

Taking the advantages and disadvantages together, we came to the following conclusions:

The treatment of choice for most perforated ulcers is immediate laparotomy and closure of the perforation.

The conservative method has a definite place in the treatment when (*a*) the diagnosis is in doubt between a perforation and a condition in which operation would be contra-indicated, such as coronary thrombosis or diaphragmatic pleurisy; (*b*) the patient's condition, whether as a result of the perforation or other causes, makes an operation inadvisable; (*c*) the signs are indefinite and a large perforation with much soiling of the peritoneal cavity is unlikely; or (*d*) good surgical facilities are not immediately available, as in ships at sea.

A TRIAL OF β-NAPHTHYLDI-2-CHLOROETHYLAMINE (R48) IN LEUKÆMIA, HODGKIN'S DISEASE, AND ALLIED DISEASES

W. B. MATTHEWS
M.A., D.M. Oxfd, M.R.C.P.
LATE RESIDENT MEDICAL OFFICER, CHURCHILL HOSPITAL, OXFORD

SINCE Gilman and Philips (1946) and Rhoads (1946) reported on the therapeutic action of the nitrogen mustards methyl-bis(β-chloroethyl)amine (HN2) and tris (β-chloroethyl)amine (HN3), these compounds have been the subject of extended trials. Published results, though differing in detail, have uniformly confirmed that the nitrogen mustards can produce considerable, but always temporary, benefit in many cases of Hodgkin's disease, lymphosarcoma, chronic leukæmia, and allied disorders, and that the factors limiting their use are depressant action on the bone-marrow and the thromboses following repeated intravenous injections. These encouraging but imperfect results naturally led to the hope that more selective and less toxic agents might be derived from the original comparatively simple compounds.

The results of clinical trials with two complex aliphatic nitrogen mustards, SK136 and SK137, were disappointing (Burchenal 1948), and Craver (1948) concluded that none of the congeners of nitrogen mustard examined at the Sloan Kettering Institute had proved superior to HN2. Haddow et al. (1948) prepared a large series of aromatic nitrogen mustards and, from a study of their inhibitory action on animal tumours, selected two of the most promising for clinical trial. Preliminary trials (Haddow 1948) soon showed that one of these compounds, bis(β-chloroethyl)aniline (R74) had an unduly depressant action on the bone-marrow. Results with β-naphthyldi-2-chloroethylamine (R48) were, however, so encouraging that clinical trials on a larger scale were organised at several centres through the Medical Research Council, and the following is a report on that carried out at Oxford.

CLINICAL MATERIAL

Seventeen patients were treated with R48. Among these were five cases of Hodgkin's disease, two of reticulosarcoma, two of acute leukæmia in adults, three of chronic myeloid leukæmia, four of chronic lymphatic leukæmia, and one of polycythæmia vera. All but one of the patients were admitted to hospital at the beginning of the trial, and a close watch was kept on the leucocyte-count. Those patients whose clinical condition permitted and in whom there had been no sharp reaction of the bone-marrow during the first 2 weeks, continued treatment as outpatients, being seen at weekly intervals.

ADMINISTRATION AND DOSAGE

R48 was given by mouth in tablets each containing 100 mg. The tablets were chewed before being swallowed and were taken after meals. The taste was inoffensive. R48 is inactivated by exposure to light, and precautions were taken to avoid this as much as possible.

The daily dose never exceeded 600 mg., and in all the conditions treated 300–400 mg. in divided doses was generally used in adults. The only child in the series, aged 7 years, was given 100 mg. daily or on alternate days. It was at first hoped that any therapeutic response might be maintained by continued smaller doses. This was not found to be possible, for such doses were either ineffective or produced toxic effects without any additional benefit. R48 was therefore given in courses with intervals during which no treatment was given. The duration of each course was determined by the response of the leucocyte-count and varied within wide limits. In patients with a non-leukæmic blood picture it was thought safe to proceed until the leucocyte-count fell to about 3000 per c.mm, though treatment was sometimes stopped above this level. In chronic leukæmia the aim, not always achieved, was to reduce the leucocyte-count to about 20,000 per c.mm. This comparatively high figure was subsequently justified for in some patients the number of leucocytes continued to fall for some weeks after treatment had been stopped. In cases where further trial was considered justified repeated courses were given—in Hodgkin's disease when the leucocyte-count had returned to normal, and in chronic leukæmia when a rise in the leucocyte-count, considered in conjunction with the clinical condition, indicated the need for further treatment. On roughly comparable doses the average duration of a course in Hodgkin's disease was 48 days (range 19–75); in chronic myeloid leukæmia 45 days (range 14–152); and in chronic lymphatic leukæmia 20 days (range 11–29). The patient with polycythæmia was given 400 mg. daily for 63 days, and the two patients with reticulosarcoma received the same dose for 11 and 36 days.

TOXIC EFFECTS

Gastric disturbances were less common and less severe with R48 than with HN2, which produces repeated vomiting in a high proportion of cases. In the present series six patients experienced no such symptoms, and a further six suffered only from slight intermittent nausea, usually confined to the first week of treatment. Of the remainder, two had an isolated bout of repeated

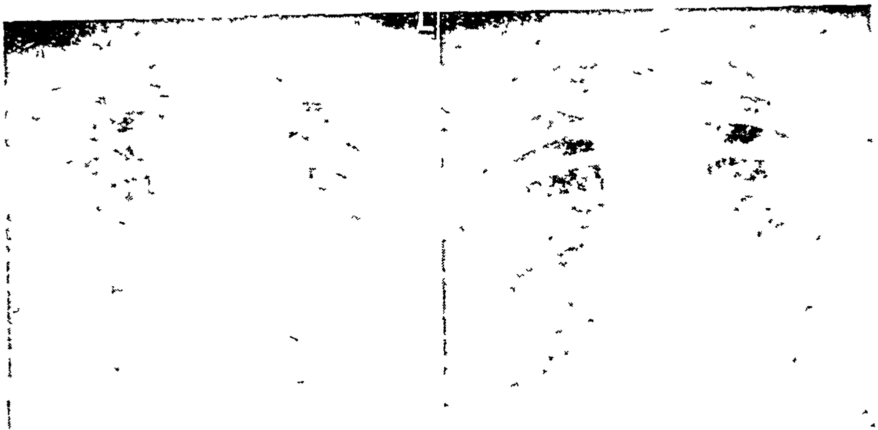

Fig. 1—Hodgkin's disease, before and after treatment with R48. Case 3 showing considerable shrinkage of mediastinal lymph-nodes.

aiting at one stage of a procted course of treatment, l one patient with acute kæmia vomited frequently ring the last few days of life, ough this could not with tainty be attributed to the 48. Two patients experienced ore protracted nausea and frequent vomiting interittently throughout treatment, d in one of them the treatent had to be stopped on this count. These gastric symptoms d not bear any fixed relation the time of swallowing the blets and were thought to be milar to the delayed vomiting fter HN2 and to radiation ickness.

Haddow (1948) reported hæmorrhagic cystitis in wo patients in his preliminary trial of R48. In the resent trial one patient developed a minor degree of ysuria with microscopic blood in the urine. The ondition cleared spontaneously and treatment was not nterrupted. Another patient, an elderly man who was known to have a mild chronic cystitis secondary to prostatic hypertrophy, experienced no ill effects from his first course of treatment but developed severe dysuria after the first dose of his second course; no blood was found in the urine, and it is doubtful if his symptoms were due to R48. Cystitis has not been reported as a complication of intravenous nitrogen-mustard therapy, and it seems possible that it is due to the aromatic radicle of R48, since β-naphthylamine is a well-known industrial hazard, producing hæmaturia and possibly carcinoma of the bladder.

A suggestive observation was that three of four women previously menstruating regularly developed amenorrhœa within a few weeks of beginning a course of R48, when their clinical condition did not suggest that this might be caused by their disease. Menstruation did not return before death, nine months later, in two patients, and was still absent a year later in the third, though she was otherwise in good clinical condition. Unfortunately it is impossible to draw any conclusion from the necropsy findings; but, in view of the profound effects of the mustards on the germ plasm and on proliferating tissue generally, it is not improbable that protracted administration of R48 might inhibit ovulation or endometrial proliferation. No effect on the size or function of the testes was observed.

Hepatic function was not tested routinely, but there was no clinical evidence that this was impaired.

EFFECTS ON PERIPHERAL BLOOD

The therapeutic effects of R48 on the leucocyte-count in leukæmia are considered below, but such effects in patients with Hodgkin's disease, reticulosarcoma, and polycythæmia are, of course, undesirable. The leucocyte-count fell in each of eleven courses of treatment in eight patients with these diseases. In ten of these courses the fall was gradual and largely calculable; hence no anxiety was experienced in seeing these patients at weekly intervals. In one man in the terminal stages of reticulosarcoma there was a precipitous fall. Treatment was stopped when the count was 2800 per c.mm., but the fall continued, reaching 550 per c.mm. three days later. One other patient developed a profound neutropenia 2 weeks after the end of a course of treatment. Both patients were given penicillin, no infection occurred, and the leucocyte-count returned promptly to normal. In general the granulocytes and lymphocytes decreased concurrently; but when treatment was stopped the granulocytes sometimes continued to decrease while the lymphocytes increased.

The platelets responded in an irregular manner, but in all cases their number fell. In one case the platelet-count fell to 55,000 per c.mm. a fortnight after treatment had been stopped; this fall coincided with an epistaxis, the only hæmorrhagic manifestation attributable to R48. Recovery to normal levels was always prompt.

In Hodgkin's disease and reticulosarcoma no significant effect on the hæmoglobin level or red-cell count was observed. No anæmia was produced, and there was no pronounced amelioration of any anæmia already present.

Sternal-marrow biopsy in a few patients before and after treatment indicated that, in common with HN2, R48 acts on the primitive cells of the myeloid series and not on the mature forms in the peripheral blood.

THERAPEUTIC RESULTS

Hodgkin's Disease

Five patients with Hodgkin's disease were treated with R48. These patients exhibited a wide range of manifestations of the disease, ranging from early disease localised in the cervical lymph-nodes to extensive radio-resistant visceral involvement. Three patients received 2 courses of treatment, and two patients a single course. Any improvement gained by the first course was maintained

RESULTS OBTAINED WITH R48 IN HODGKIN'S DISEASE

Case no	Improved	Unimproved	Duration of improvement from stopping treatment (weeks)
1	Subjective improvement, gain in weight, spleen became impalpable, peripheral nodes reduced, soft tissue tumour reduced	Abdominal masses unaffected, lesions of ribs unaffected, pleural effusion developed during treatment	4
2	Subjective improvement, spleen and peripheral nodes became impalpable	Mediastinal nodes and pleural effusion unaffected	8
3	Subjective improvement, gain in weight, fever abolished, peripheral and mediastinal nodes reduced	Pulmonary infiltration unaffected	5
4	Subjective improvement, fever abolished, peripheral nodes reduced		4
5	Peripheral nodes reduced, spleen became impalpable	Continued loss of weight	7

in the interval between courses; hence no sharp distinction can be drawn between the effects of each course, and the effects of the total treatment with R48 will be considered. This is summarised in the accompanying table, and it can be seen that some improvement, often of important degree (fig. 1), was obtained in each case. Such improvement was not usually obvious until 2–3 weeks after the start of treatment and was never so rapid as that often seen after the injection of HN2. In no case, however, was a complete clinical remission produced, and relapse occurred within a few weeks of stopping treatment. It was noted that the leucocyte-count returned to normal while any clinical improvement was still maintained. Since leucopenia seemed to be the only limiting factor in the use of R48, it was hoped that by repeated courses further regression of the disease might be obtained. It was found, however, in those cases receiving two courses, that this was not so. It seemed that R48 could produce a certain degree of improvement, but that further treatment had then no beneficial effect and finally had to be abandoned because of a return of leucopenia. The degree of improvement did not seem to be related to the degree of leucopenia.

Reticulosarcoma

Two patients with reticulosarcoma, both of whom had earlier responded partially to radiotherapy, were treated with R48. Although in one case there was some regression of unimportant lesions, in neither case was the inexorable growth of the main tumour affected in any way, and both patients died.

Acute Leukæmia

Two adults with acute myeloid leukæmia were treated. In one a fall in the leucocyte-count was produced, but this was entirely at the expense of the normal cells, and there was no concomitant clinical benefit. The disease in the other patient pursued a rapidly fatal course unaffected by R48.

Chronic Myeloid Leukæmia

Three cases of chronic myeloid leukæmia were treated. In two previously untreated cases good initial clinical and hæmatological remissions were produced, with a fall in the leucocyte-count, an improvement in the differential count, a rise in hæmoglobin, a reduction in the size of the spleen, and an increase in well-being. There was no doubt that real improvement occurred, as opposed to a mere fall in the leucocyte-count, for in one patient the hæmoglobin rose 30% and the spleen was reduced by 12 cm., and in the other patient the hæmoglobin rose 40% and the spleen shrank by 15 cm. In the first of these patients a further course was required after 12 weeks, and though improvement again occurred the response was less satisfactory and the trial was abandoned.

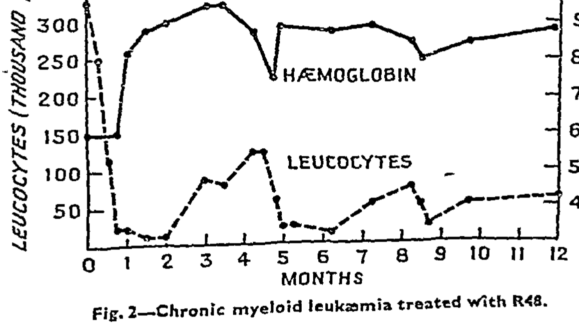

Fig. 2—Chronic myeloid leukæmia treated with R48.

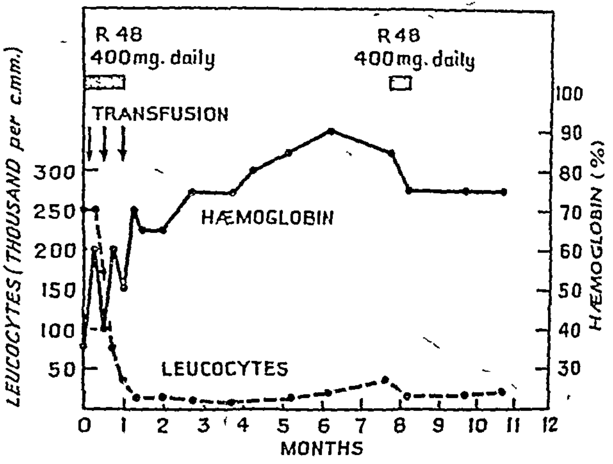

Fig. 3—Chronic lymphatic leukæmia treated with R48.

The second patient responded repeatedly, and three remissions, each of 3 or 4 months' duration, were produced (fig. 2). The third patient had previously been treated with X rays, with lessening response, and the response to R48 was also disappointing. After a long course and heavy dosage a rise of 20% in the hæmoglobin and a fall in the leucocyte-count from 290,000 to 67,000 per c.mm. were produced, but no further improvement occurred. Within 3 weeks after treatment had been stopped the patient entered the acute stage of her disease, and she soon died.

Chronic Lymphatic Leukæmia

Four cases of chronic lymphatic leukæmia were treated. In two, good and repeatable remissions were obtained. Again there was no doubt that real improvement took place, as may be seen from the following case-record.

A station-master, aged 59, was admitted to the Radcliffe Infirmary under Professor Witts with a history of fluctuating swellings in the neck, axillæ, and groins for the past year, and of recent increasing fatigue. He had a generalised enlargement of lymph-nodes, a spleen measuring 20 cm. from tip to costal margin, and an enlarged liver. He had pyrexia up to 104°F and was very weak and wasted. Before treatment his leucocyte-count was 251,000 per c.mm., nearly all lymphocytes, and his hæmoglobin 35%. He was given 11·8 g. of R48 in 29 days, with no toxic effects. When treatment was stopped, the leucocyte-count had fallen to 37,000 per c.mm., but the hæmoglobin was still barely maintained by transfusions. He was discharged from hospital and seen frequently as an outpatient. In the following months he gradually improved, and 5 months after treatment had been stopped the leucocyte-count was 18,400 per c.mm., the hæmoglobin was 90%, the spleen had shrunk by 7 cm., and there had been a general reduction in size of the lymph-nodes. He had gained 8 kg. in weight and had been in full work for two months. A subsequent rise in the leucocyte-count was treated with a further short course of R48 with good effect (fig. 3). This patient, although still presenting gross clinical and hæmatological signs of his disease, was enabled to return to full work after having been apparently moribund.

The second patient, although not so gravely ill, responded similarly. The third patient was in extremis on admission and, although her leucocyte-count fell from 860,000 to 106,000 per c.mm., she died from the effects of asthma, pneumonia, and intestinal obstruction.

The fourth patient had previously reacted with increasing severity to several courses of radiotherapy, which had produced a fall in both leucocyte-count and hæmoglobin. She was treated, perhaps unwisely, with 400 mg. of R48 daily, and there was a very rapid fall in the leucocyte-count, platelet-count, and hæmoglobin. The marrow became very hypoplastic, and, though agranulocytic angina did not develop, there can be no doubt that the anæmia produced by R48 contributed to the patient's death 6 months later. It is

possible that any form of treatment would have produced a similar reaction in view of the previous very similar response to X rays.

Polycythæmia Vera

One case of polycythæmia vera was treated. The initial red-cell count 7,700,000 per c.mm., with a hæmatocrit of 68%, was reduced to about normal figures by repeated venesection, as it was not thought wise to await any possible response to R48. A course of 24·4 g. was given in 63 days, during which the leucocyte-count fell from 16,600 to 5600 per c.mm. and the platelets from 1,100,000 to 200,000 per c.mm. The red-cell count remained at about 5,000,000 per c.mm. and the hæmatocrit at 48%. These levels were still maintained a year later and there had been no return of symptoms.

DISCUSSION

Although it was shown beyond doubt that R48 can cause partial regression of Hodgkin's disease, the therapeutic results in this condition must be considered disappointing. Such observations are difficult to control, but the results were certainly no better than those to be expected with HN2. In two patients subsequent radiotherapy produced superior results, and it seems established that R48 is unsuitable for the treatment of early localised Hodgkin's disease. Where widespread lesions are present, the comparative lack of unpleasant toxic effects may be an advantage; but dramatic results are not to be expected, and it is doubtful if R48 represents any advance in the treatment of Hodgkin's disease.

The two cases of reticulosarcoma do not comprise a full trial, for this disease is very variable in its response both to HN2 and to radiotherapy. There was, however, no evidence that R48 was of any value.

The lack of response of the two cases of acute leukæmia was not surprising and merely emphasises the resistance of the acute condition to those agents which are of value in the treatment of chronic leukæmia.

In four cases of chronic leukæmia R48 produced excellent initial remissions unaccompanied by toxic effects of any kind. After an interval of 11–28 weeks further treatment was required, and in all cases remissions were repeatable. It is here that the value of R48 seems to lie. It is not claimed that greater improvement can be obtained than with other forms of treatment, although the response in the case described above would have been gratifying with any treatment; but, when no toxic symptoms are produced, the administration of tablets which produce a smooth and easily controlled response presents obvious advantages. On the other hand, remissions are short-lived, and, if toxic symptoms develop, it is not worth while persevering with R48. It must be pointed out that these four cases were previously untreated, and there is no evidence that R48 will produce much improvement when other treatment has failed.

The one case of polycythæmia vera treated was still in remission a year later, which could scarcely be attributed to venesection at the beginning of treatment. A year's remission with no toxic effects is a worthwhile achievement, but far more experience would be required for a full assessment of R48 in this condition.

Short of cure, the aim in the development of palliative agents in Hodgkin's disease and leukæmia has been to separate their toxic and therapeutic actions. The nitrogen mustards present a large field for manipulation of chemical structure; but, so far as is known, biological activity depends on the presence of two β-chloroethyl groups attached to one or more nitrogen atoms (Anslow et al. 1947, Haddow et al. 1948). It is understandable that the chemical structure into which this group is introduced might affect its site or speed of action, but nevertheless the available evidence suggests that both the toxic and beneficial effects depend on the cytotoxic action of the mustards on proliferating tissue. The present trial suggests that the substitution of the β-naphthyl for the methyl radicle influences the speed but not the selectivity of the action of nitrogen mustard.

SUMMARY

Seventeen patients were treated with β-naphthyldi-2-chloroethylamine (R48) by mouth, the usual dose being 300–400 mg. daily.

Five cases of Hodgkin's disease all showed some improvement, but the results were on the whole disappointing.

Two cases of reticulosarcoma and two of acute leukæmia did not respond.

Three cases of chronic myeloid leukæmia were treated. with good remissions in two.

Four cases of chronic lymphatic leukæmia were treated, with good remissions in two.

One case of polycythæmia vera was still in remission a year after treatment.

Toxic symptoms included relatively mild and infrequent gastric disturbances, and cystitis in one patient.

There was an invariable depression of the leucocyte-count and platelet-count.

It was concluded that the action of R48 was essentially similar to that of nitrogen mustard (HN2) but slower and more easily controlled.

FLAXEDIL IN LARYNGEAL INTUBATION

A. G. Doughty
M.B. Lond., D.A.
SENIOR REGISTRAR, DEPARTMENT OF ANÆSTHETICS,
ST. THOMAS'S HOSPITAL, LONDON

The effect of *d*-tubocurarine chloride in facilitating intubation of the larynx was first mentioned by Gray (1946). Bourne (1947) showed that for nearly all surgery of the head and neck in adults satisfactory anæsthesia could be maintained with nitrous oxide and oxygen following intubation under thiopentone and curare. The advantages of this method are: (1) an easy atraumatic intubation; (2) toleration of the tube with gas and oxygen alone, or in a few cases with minimal intravenous or volatile supplementary agents; (3) absence of sequelæ due to a traumatic intubation or to a nauseating volatile agent; (4) non-inflammable anæsthetic mixture; (5) quick recovery of cough reflex and consciousness; and (6) a considerable saving of time.

Bourne's method, with various modifications, has been used extensively during the last two years for operations requiring intubation and maintenance of anæsthesia at a light level. However, there are certain disadvantages: (1) the effect of the curare may occasionally last longer than the operation; (2) a comparatively large dose of thiopentone is required with the curare to produce satisfactory relaxation of the vocal cords: and (3) many in the interval between courses; hence no sharp distinction can be drawn between the effects of each course, and the effects of the total treatment with R48 will be considered. This is summarised in the accompanying table, and it can be seen that some improvement, often of important degree (fig. 1), was obtained in each case. Such improvement was not usually obvious until 2–3 weeks after the start of treatment and was never so rapid as that often seen after the injection of HN2. In no case, however, was a complete clinical remission produced, *and relapse occurred within a few weeks of* stopping treatment. It was noted that the leucocyte-count returned to normal while any clinical improvement was still maintained. Since leucopenia seemed to be the only limiting factor in the use of R48, it was hoped that by repeated courses further regression of the disease might be obtained. It was found, however, in those cases receiving two courses, that this was not so. It seemed that R48 could produce a certain degree of improvement, but that further treatment had then no beneficial effect and finally had to be abandoned because of a return of leucopenia. The degree of improvement did not seem to be related to the degree of leucopenia.

Reticulosarcoma

Two patients with reticulosarcoma, both of whom had earlier responded partially to radiotherapy, were treated with R48. Although in one case there was some regression of unimportant lesions, in neither case was the inexorable growth of the main tumour affected in any way, and both patients died.

Acute Leukæmia

Two adults with acute myeloid leukæmia were treated. In one a fall in the leucocyte-count was produced, but this was entirely at the expense of the normal cells, and there was no concomitant clinical benefit. The disease in the other patient pursued a rapidly fatal course unaffected by R48.

Chronic Myeloid Leukæmia

Three cases of chronic myeloid leukæmia were treated. In two previously untreated cases good initial clinical and hæmatological remissions were produced, with a fall in the leucocyte-count, an improvement in the differential count, a rise in hæmoglobin, a reduction in the size of the spleen, and an increase in well-being. There was no doubt that real improvement occurred, as opposed to a mere fall in the leucocyte-count, for in one patient the hæmoglobin rose 30% and the spleen was reduced by 12 cm., and in the other patient the hæmoglobin rose 40% and the spleen shrank by 15 cm. In the first of these patients a further course was required after 12 weeks, and though improvement again occurred the response was less satisfactory and the trial was abandoned.

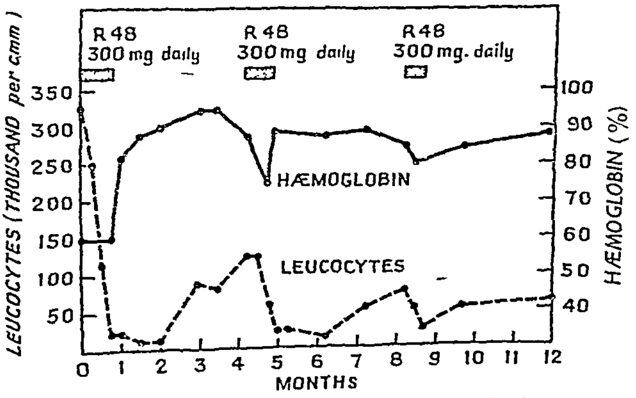

Fig. 2—Chronic myeloid leukæmia treated with R48.

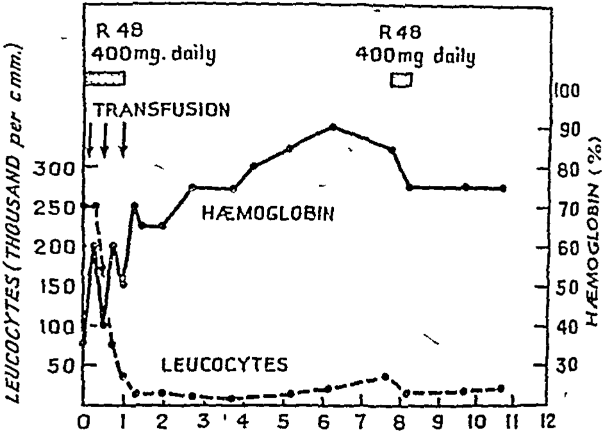

Fig. 3—Chronic lymphatic leukæmia treated with R48.

The second patient responded repeatedly, and three remissions, each of 3 or 4 months' duration, were produced (fig. 2). The third patient had previously been treated with X rays, with lessening response, and the response to R48 was also disappointing. After a long course and heavy dosage a rise of 20% in the hæmoglobin and a fall in the leucocyte-count from 290,000 to 67,000 per c.mm. were produced, but no further improvement occurred. Within 3 weeks after treatment had been stopped the patient entered the acute stage of her disease, and she soon died.

Chronic Lymphatic Leukæmia

Four cases of chronic lymphatic leukæmia were treated. In two, good and repeatable remissions were obtained. Again there was no doubt that real improvement took place, as may be seen from the following case-record.

A station-master, aged 59, was admitted to the Radcliffe Infirmary under Professor Witts with a history of fluctuating swellings in the neck, axillæ, and groins for the past year, and of recent increasing fatigue. He had a generalised enlargement of lymph-nodes, a spleen measuring 20 cm. from tip to costal margin, and an enlarged liver. He had pyrexia up to 104°F and was very weak and wasted. Before treatment his leucocyte-count was 251,000 per c.mm., nearly all lymphocytes, and his hæmoglobin 35%. He was given 11·8 g. of R48 in 29 days, with no toxic effects. When treatment was stopped, the leucocyte-count had fallen to 37,000 per c.mm., but the hæmoglobin was still barely maintained by transfusions. He was discharged from hospital and seen frequently as an outpatient. In the following months he gradually improved, and 5 months after treatment had been stopped the leucocyte-count was 18,400 per c.mm., the hæmoglobin was 90%, the spleen had shrunk by 7 cm., and there had been a general reduction in size of the lymph-nodes. He had gained 8 kg. in weight and had been in full work for two months. A subsequent rise in the leucocyte-count was treated with a further short course of R48 with good effect (fig. 3). This patient, although still presenting gross clinical and hæmatological signs of his disease, was enabled to return to full work after having been apparently moribund.

The second patient, although not so gravely ill, responded similarly. The third patient was in extremis on admission and, although her leucocyte-count fell from 860,000 to 106,000 per c.mm., she died from the effects of asthma, pneumonia, and intestinal obstruction.

The fourth patient had previously reacted with increasing severity to several courses of radiotherapy, which had produced a fall in both leucocyte-count and hæmoglobin. She was treated, perhaps unwisely, with 400 mg. of R48 daily, and there was a very rapid fall in the leucocyte-count, platelet-count, and hæmoglobin. The marrow became very hypoplastic, and, though agranulocytic angina did not develop, there can be no doubt that the anæmia produced by R48 contributed to the patient's death 6 months later. It is

possible that any form of treatment would have produced a similar reaction in view of the previous very similar response to X rays.

Polycythæmia Vera

One case of polycythæmia vera was treated. The initial red-cell count 7,700,000 per c.mm., with a hæmatocrit of 68%, was reduced to about normal figures by repeated venesection, as it was not thought wise to await any possible response to R48. A course of 24·4 g. was given in 63 days, during which the leucocyte-count fell from 16,600 to 5600 per c.mm. and the platelets from 1,100,000 to 200,000 per c.mm. The red-cell count remained at about 5,000,000 per c.mm. and the hæmatocrit at 48%. These levels were still maintained a year later and there had been no return of symptoms.

DISCUSSION

Although it was shown beyond doubt that R48 can cause partial regression of Hodgkin's disease, the therapeutic results in this condition must be considered disappointing. Such observations are difficult to control, but the results were certainly no better than those to be expected with HN2. In two patients subsequent radiotherapy produced superior results, and it seems established that R48 is unsuitable for the treatment of early localised Hodgkin's disease. Where widespread lesions are present, the comparative lack of unpleasant toxic effects may be an advantage; but dramatic results are not to be expected, and it is doubtful if R48 represents any advance in the treatment of Hodgkin's disease.

The two cases of reticulosarcoma do not comprise a full trial, for this disease is very variable in its response both to HN2 and to radiotherapy. There was, however, no evidence that R48 was of any value.

The lack of response of the two cases of acute leukæmia was not surprising and merely emphasises the resistance of the acute condition to those agents which are of value in the treatment of chronic leukæmia.

In four cases of chronic leukæmia R48 produced excellent initial remissions unaccompanied by toxic effects of any kind. After an interval of 11–28 weeks further treatment was required, and in all cases remissions were repeatable. It is here that the value of R48 seems to lie. It is not claimed that greater improvement can be obtained than with other forms of treatment, although the response in the case described above would have been gratifying with any treatment; but, when no toxic symptoms are produced, the administration of tablets which produce a smooth and easily controlled response presents obvious advantages. On the other hand, remissions are short-lived, and, if toxic symptoms develop, it is not worth while persevering with R48. It must be pointed out that these four cases were previously untreated, and there is no evidence that R48 will produce much improvement when other treatment has failed.

The one case of polycythæmia vera treated was still in remission a year later, which could scarcely be attributed to venesection at the beginning of treatment. A year's remission with no toxic effects is a worthwhile achievement, but far more experience would be required for a full assessment of R48 in this condition.

Short of cure, the aim in the development of palliative agents in Hodgkin's disease and leukæmia has been to separate their toxic and therapeutic actions. The nitrogen mustards present a large field for manipulation of chemical structure; but, so far as is known, biological activity depends on the presence of two β-chloroethyl groups attached to one or more nitrogen atoms (Anslow et al. 1947, Haddow et al. 1948). It is understandable that the chemical structure into which this group is introduced might affect its site or speed of action, but nevertheless the available evidence suggests that both the toxic and beneficial effects depend on the cytotoxic action of the mustards on proliferating tissue. The present trial suggests that the substitution of the β-naphthyl for the methyl radicle influences the speed but not the selectivity of the action of nitrogen mustard.

SUMMARY

Seventeen patients were treated with β-naphthyldi-2-chloroethylamine (R48) by mouth, the usual dose being 300–400 mg. daily.

Bourne (1947) showed that for nearly all surgery of the head and neck in adults satisfactory anæsthesia could be maintained with nitrous oxide and oxygen following intubation under thiopentone and curare. The advantages of this method are: (1) an easy atraumatic intubation; (2) toleration of the tube with gas and oxygen alone, or in a few cases with minimal intravenous or volatile supplementary agents; (3) absence of sequelæ due to a traumatic intubation or to a nauseating volatile agent; (4) non-inflammable anæsthetic mixture; (5) quick recovery of cough reflex and consciousness; and (6) a considerable saving of time.

Bourne's method, with various modifications, has been used extensively during the last two years for operations requiring intubation and maintenance of anæsthesia at a light level. However, there are certain disadvantages: (1) the effect of the curare may occasionally last longer than the operation; (2) a comparatively large dose of thiopentone is required with the curare to produce satisfactory relaxation of the vocal cords; and (3) many cases have required artificial ventilation for varying periods after intubation, and, even when spontaneous respiration has started, the respiratory excursion has been inadequate.

By the use of 'Flaxedil' (tri-(β-diethylaminoethoxy)-benzene triethiodide) in place of *d*-tubocurarine chloride, Bourne's technique has been modified to produce a method of anæsthesia for head and neck surgery which avoids the disadvantages of the former method.

Flaxedil is a synthetic curarising agent, the clinical uses of which were reported by Mushin et al. (1949). Lamoureux and Bourgeois-Gavardin (1949) found that flaxedil facilitated laryngeal intubation in 50 operation cases of various types. Mushin et al. considered that a dose of 80 mg. of flaxedil was equivalent in curarising activity to 15 mg. of *d*-tubocurarine chloride. This dose, which is contained in a 2 ml. ampoule of flaxedil, was used in all adult patients in the series described in this article, irrespective of age, weight, or physical condition.

The dosage of thiopentone given with the flaxedil requires explanation. To show that flaxedil is effective in facilitating intubation, the dose of barbiturate must be small. However, a fixed dose given to each patient would be an overdose for some and inadequate for others. It was therefore decided to adjust the dose for each patient *according to that patient's reaction to the* barbiturate. When the intravenous barbiturates were introduced, the proper induction dose was considered to be twice that required to send the patient to sleep. This was the dose used in this investigation. Thus as little as 0·25 g. and as much as 1 g. has been used in this series.

PROCEDURE

Each patient was given 5% thiopentone intravenously at a rate allowed by injecting through a no. 16 S.W.G. needle without undue pressure on the plunger. The patient was engaged in conversation. When the patient went to sleep, the amount of barbiturate injected was noted and the syringe detached from the needle. Flaxedil 80 mg. was injected through the same needle, followed by the injection of a further dose of thiopentone equal to the amount already injected. The syringe and needle were laid aside, and the patient was given pure oxygen by inhalation for half a minute. If the patient was breathing, the respirations were assisted by gentle pressure on the reservoir bag with each inspiration. If the patient was apnœic, the lungs were artificially inflated. About 1–1$^1/_2$ minutes after injection the flaxedil seemed to be exerting its full effect. The jaw was usually relaxed and the glottis open. A Macintosh laryngoscope was then passed and the larynx sprayed with 2% amethocaine. The tube was then passed and connected to a Boyle's machine, and anæsthesia maintained with nitrous oxide 75% and oxygen 25%.

Since intubation took place immediately after the larynx had been sprayed, it is unlikely that the surface analgesic had sufficient time to act and thus facilitate the intubation. The spraying, however, not only enabled the tube to be tolerated by the larynx and trachea under light anæsthesia but also, which is more to the purpose of this investigation, gave some indication of the irritability of the larynx after the thiopentone and flaxedil. In some cases the impact of the spray produced no reaction of the vocal cords, in some a slight temporary adduction, and in a few a temporary spasm. The ease of intubation and the degree of cough reaction following intubation were also noted.

RESULTS

The degree to which flaxedil facilitated the intubations and depressed the reactivity of the larynx and cough reflex was estimated by classifying each intubation into one of four groups as follows:

	Group I	*Group II*	*Group III*	*Group IV*
Cords	Open	Open	Active	
Reaction to spray	Nil	Slight	Vigorous	
Ease of intubation	Very easy	Easy	Difficult	Unsuccessful intubation
Cough after intubation	Nil	Slight, rapidly settled into rhythmical respiration	Considerable and long-lasting	

Any intubation which was not achieved at the first attempt was classified into group IV. Intubation was not abandoned, but more anæsthetic agent was given, or time was allowed for the surface analgesic to exert its effect.

In 136 cases the following results were obtained:

	Group I	*Group II*	*Group III*	*Group IV*
No. of cases	38 (27·9%)	71 (52·2%)	22 (16·2%)	5 (3·7%)

Thus it will be seen that the use of 80 mg. of flaxedil with small doses of thiopentone can produce conditions in which 80% of intubations may be regarded as easy (groups I and II).

It is obviously of interest to observe the number of cases in which apnœa persisted after intubation long enough to require artificial respiration. The manufacturers of flaxedil claim that, in contrast with *d*-tubocurarine chloride, muscular relaxation is produced without undue depression of diaphragmatic respiration. In 9 (7%) of the 136 cases artificial respiration was necessary. One case is instructive because of the comparison which it afforded between flaxedil and *d*-tubocurarine chloride:

A frail man of 59 underwent two plastic operations on his frontal sinuses. At the first operation he was intubated easily (group II) under thiopentone 0·5 g. and *d*-tubocurarine chloride 15 mg. He was apnœic for an hour after intubation. A week later he was intubated with equal ease, for the second operation, under the same dose of thiopentone aided by 80 mg. of flaxedil. On this occasion he was apnœic for only 2$^1/_2$ minutes.

SUPPLEMENTARY ANÆSTHESIA

In most cases no agent other than 75% nitrous oxide with 25% oxygen was used to maintain the patient in anæsthesia, but in long operations, or when the patient coughed persistently on the tube, a trace of ether or of trichlorethylene, or further small additions of intravenous thiopentone, were sufficient to ensure maintenance of a smooth anæsthesia.

EXTUBATION AND RECOVERY

Gillespie (1948) has warned that severe laryngeal spasm may follow extubation under very light anæsthesia. In the present series only 4% developed anything more than a transient spasm when the tube was removed. Recovery of consciousness was very rapid in those cases in which no additional anæsthetic agent was used apart from nitrous oxide. Every patient was followed up, and no sequelæ attributable to flaxedil were discovered.

SIDE-ACTIONS OF FLAXEDIL

Lamoureux and Bourgeois-Gavardin (1949) have reported that flaxedil caused a rise in the pulse-rate up to 100–110 in 40% of their cases. A transitory tachycardia may often accompany the induction of any form of anæsthesia, but it was also produced by single injections of flaxedil. Huguenard and Boué (1950) consider that flaxedil has a vagolytic action because of its inhibitory effect on the cough reflex. Lamoureux and Bourgeois-Gavardin suggest that the vagolytic action may also explain the tachycardia following the injection of flaxedil.

Of the present cases 33% showed a rise in the pulse-rate to 110 or more, and 16% showed a rise of 50% over the resting rate. The highest rate recorded was 140. No irregularities of the cardiac rhythm were observed; nor were any abnormalities noted, apart from tachycardia, on electrocardiography.

HISTAMINE-LIKE EFFECTS

Mushin et al. (1949) have shown in experiments on animals that flaxedil liberated less histamine ($^1/_5$–$^1/_2$) than did *d*-tubocurarine chloride. With the dose of 80 mg. used in this series neither fall of blood-pressure nor bronchospasm was observed. However, in a few cases only, a conspicuous flushing of the face was noted soon after injection, but it is difficult to say whether or not capillary oozing was much more than normal.

COMPARISON WITH DECAMETHONIUM IODIDE

The use of flaxedil naturally invites comparison with decamethonium iodide, the other synthetic curarising agent now in common use. Decamethonium iodide was used in 57 cases with the same technique of administration as described for flaxedil. However, to get a degree of relaxation to produce conditions for intubation comparable with those obtained with flaxedil, it was found necessary to give as a standard dose 4 mg. (equivalent in curarising activity to 20 mg. of *d*-tubocurarine chloride). In 57 cases the following results were obtained:

	Group I	*Group II*	*Group III*	*Group IV*
No. of cases	13 (*22·8%*)	24 (*42·1%*)	14 (*24·6%*)	6 (*10·5%*)

It will be seen that, even with a dose of decamethonium iodide with a higher curarising potency than that of 80 mg. of flaxedil, only 64·9% of cases fell into groups I and II (easy intubations). In addition, it was not surprising that nearly half the cases (47%) required artificial respiration for various periods following intubation. Of the 37 cases in which an easy intubation was carried out 21 (59%) needed artificial respiration. With flaxedil only 9 (8%) of 109 easy intubation cases required artificial respiration.

With decamethonium iodide the onset of relaxation of the jaw and vocal cords was slower than with flaxedil, and in many cases difficulty was caused by a severe clonus of the lower jaw, which sometimes prevented the insertion of the laryngoscope. Occasionally the clonus persisted for four minutes or more, by which time one would have expected decamethonium iodide to have exerted its full effect. With flaxedil no case showed jaw clonus, and the rapid onset of relaxation of the jaw was a pronounced feature in the use of flaxedil.

Patients intubated after decamethonium iodide showed a lower tolerance of the tube in the trachea, and most of them required more than nitrous oxide and oxygen to maintain rhythmical respiration without coughing.

A great disadvantage of decamethonium iodide (C10) is that neostigmine is not an effective antidote to it and that the advertised antidote—pentamethonium bromide (C5)—has been found unsatisfactory because of its inconstancy of action and its effect in lowering the blood-pressure. Thus in very short procedures it is possible that the operation may end before the respiratory depression has worn off, and the patient must remain in the operating-theatre under supervision until full respiratory efficiency has been regained. With flaxedil, in the one case in which an antidote was required, an injection of neostigmine 2·5 mg. with atropine gr. $^1/_{100}$ effectively restored full respiratory activity within a minute.

Decamethonium iodide seemed to have two advantages over flaxedil: (1) possibly because there is no liberation of histamine, there seemed to be no peripheral vasodilatation, and one would therefore expect less capillary oozing; and (2) the pulse-rate did not seem to be so much raised as with flaxedil—in fact in some cases there was bradycardia.

DISCUSSION

The principle of using a curarising agent with thiopentone and gas-and-oxygen in anæsthesia for head and neck surgery has aroused considerable controversy. It has been described as "using a steam-hammer to crack a nut" (Frankis Evans 1949). This criticism might have some substance if the mere passing of the endotracheal tube were the sole aim of the anæsthetist. However, it is necessary not only to intubate the patient without undue delay but also to produce a patient in a condition suitable for the surgeon to start operating. It is no advantage to intubate a patient within a minute or so of his loss of consciousness, if a further ten minutes must elapse before he will tolerate the tube without coughing, or will relax his jaw and fauces sufficiently to enable a pack to be inserted, or to enable intra-oral operations to be done.

The ideal conditions required for a rapid safe easy atraumatic intubation are: (1) a perfect view of the vocal cords; (2) an open glottis; and (3) unreactive vocal cords. After intubation the patient should settle down rapidly on the tube, there should be no tendency to cough, and light anæsthesia should be maintained. The surgeon should be able safely to use diathermy. Recovery should be rapid, there should be no sequelæ due to trauma during intubation, and post-anæsthetic nausea should be minimal.

Few would quarrel with the use of ether to produce the conditions necessary for a safe, easy, atraumatic intubation. Yet to achieve open and unreactive cords with a relaxed lower jaw, plane-III anæsthesia is required. This is a depth of narcosis well beyond that required for the ordinary head and neck operation. The patient has been subjected to the toxic effect of ether on the liver and kidneys, and is likely to suffer from post-anæsthetic nausea, simply in order to produce relaxation of the jaw and depression of the laryngeal reflexes. These aims can be attained far more expeditiously and with less cost to the patient by the use of a small dose of thiopentone and a curarising agent. In addition, with ether anæsthesia the surgeon cannot safely use diathermy, and an induction with ether to the third plane is time-consuming.

Thiopentone is used by itself extensively to achieve a rapid intubation. However, apart from the risk of a severe laryngeal spasm which may result from an attempt at intubation, a successful intubation is often followed by a vigorous reflex reaction marked by prolonged breath-holding, bronchospasm, and congestion of the head and neck. True, these reactions may subside after a time, or their subsidence may be hastened by further doses of thiopentone, but the cost to the patient after the initial severe strain on the cardiovascular system may be circulatory depression due to a large dose of thiopentone, and a delayed recovery from the anæsthetic.

Cyclopropane is not always satisfactory, for, though a relaxed jaw and open unreactive cords may rapidly be obtained, maintenance requires a circle absorber. The difficulty of securing the heavy circle tubing and obtaining a gas-tight circuit, particularly with a nasal tube, makes this method clumsy. There is also increased bleeding from the wound, the explosion risk is present, and nausea and vomiting are not uncommon sequelæ.

It is suggested that thiopentone and gas-and-oxygen, with a curarising agent, approaches the ideal more closely than any other method. Of the curarising agents now available flaxedil appears to be the most satisfactory. Its rapid action in producing relaxation of the lower jaw, and in depressing the activity of the larynx, allows an easy atraumatic intubation. In most cases its effect passes so rapidly that full diaphragmatic respiration is unimpaired. In those cases in which artificial respiration was required, only in one was it necessary for more than four minutes.

It is not maintained that the technique described for using flaxedil has been perfected. More experience is necessary to balance the dose of flaxedil and thiopentone so as to secure the best conditions for an easy intubation without unduly depressing respiration. It is emphasised, however, that the required dose of thiopentone should be commensurate with the size and physical condition of the patient, and is often rather less than one would expect. It would probably be estimated more accurately by the judgment of the individual anæsthetist, based on experience, than on the rule-of-thumb method described in this article. However, this method of estimation has been shown to be reasonably reliable in practice, and may therefore serve as a useful guide.

SUMMARY

The use of flaxedil in facilitating laryngeal intubation is described.

Its effect for this purpose is compared with that of decamethonium iodide.

The advantages of the use of curarising agents in facilitating intubation are discussed in comparison with other methods.

My thanks are due to Dr. W. D. Wylie and Dr. J. G. Bourne for their helpful criticisms and suggestions; to those members of the department of anæsthetics, St. Thomas's Hospital, who have anæsthetised the patients and kept records of the cases on which this article is based; and to Miss J. Davenport for the secretarial work which she has undertaken for me. Messrs. May & Baker Ltd. furnished me with the flaxedil used in this investigation.

USE OF ALBUMIN-ACTIVE ANTISERA IN RHESUS TYPING

E. M. STIRK
M.B. Birm.
ASSISTANT PATHOLOGIST, THE ROYAL HOSPITAL, WOLVERHAMPTON

THERE is a steady rise in the number of people who have at some time or other received a blood-transfusion, and, since the range of conditions for which transfusions are given is still widening, many of them stand a fair chance of receiving blood again later in life. On account of shortage of typing antisera many Rh-negative people have received Rh-positive blood and are in danger of developing severe reactions from sensitisation on further transfusion. The Rh typing of all patients before transfusion thus becomes increasingly necessary, but this is impracticable because the supplies of Rh-typing antisera active on saline red-cell suspensions are being largely used in testing donors to the National Blood Transfusion Service and in antenatal tests (*British Medical Journal* 1950).

In these circumstances it seems remarkable that little use has been made of the abundant supply of Rh antisera active on red cells suspended in albumin solution. These antisera containing "blocking" or "incomplete" antibodies can be obtained from a high proportion of mothers sensitised by a Rh-positive fœtus.

When we started the routine Rh typing of hospital patients in Wolverhampton in October, 1948, we tried, for reasons of economy, the Chown (1944) capillary-tube technique. This method was tried for four to six months, but our results were not sufficiently accurate to warrant its continuance. Several false-positive results were produced by clotting of the cell suspension in the capillary tube; this usually occurred with blood freshly taken from patients with postpartum hæmorrhage or some similar acute hæmorrhagic emergency. False-negative results were encountered and caused us considerable inconvenience by creating an unnecessary demand for the interim use of Rh-negative blood until the patient's Rh type had been corrected by the Regional Blood Transfusion Laboratory. In America the risk of inaccurate results with this method appears to be recognised, and DeGowin et al. (1949) say that it should be used only by experienced workers.

Since we could not obtain enough saline-active antisera (S.A.A.) for typing all hospital patients before transfusion we started using albumin-active antisera (A.A.A.) obtained locally from mothers who had recently given birth to infants with hæmolytic disease. In a year we have collected seven suitable sera. For our purposes it was sufficient to withdraw 30–40 ml. from each mother, but much large quantities could have been obtained. Most of our sera are of a fairly high titre, but one with a titre no greater than 1 : 4 against homozygous Rh-positive cells gives very satisfactory results.

METHODS

The blood is obtained within two or three weeks of parturition. It is withdrawn by venepuncture into a clean dry sterile test-tube, allowed to clot at room-temperature, and then placed in the cold room at 4°C for three or four days until the clot has fully retracted. The separated serum is next pipetted off and stored in small test-tubes in the freezing cabinet at −10°C. These conditions of storage are imperative for preserving the potency of anti-Rh sera. If the serum is stored at 4°C in the blood-bank, deterioration quickly sets in, and contamination with organisms surviving at this temperature may lead to panagglutination.

Serum for day-to-day use is withdrawn in 2–3 ml. amounts from the stock tubes as required. In doing this it is important to thaw the frozen serum at a temperature not exceeding 37°C and to mix it well before withdrawal, because anti-Rh antibodies tend to be more concentrated in the lower layers of frozen serum (Keynes et al. 1949a).

The tests are performed in duplicate for each patient with different sera. Since anti-A and anti-B agglutinins are not absorbed from the typing sera, due regard must be paid to compatibility of the patient's ABO group and that of the test sera selected. Antisera of group A can usually be used against both group-A and group-O cells, and those belonging to group AB can be used against all unknown cells.

The Test

Pipette one drop of the recipient cells from clotted blood and without freeing them from their serum, suspend the cells in 20% commercial bovine albumin to form an approximately 2% solution. To a small drop of this suspension, freed from fragments of clot, in a round-bottomed precipitin tube add an equal volume of antiserum. Incubate the suspension for an hour in a water-bath at 37°C, transfer it to a slide without a coverslip and read the result microscopically.

The results are expressed, according to the terms adopted by Mollison et al. (1948), from — to *w* (weak), +, ++, +++, and ++++ degrees of agglutination. Most of our readings fell into the categories ++ and +++, so there was little risk of confusion with rouleaux formation.

In an emergency rapid results can be obtained by using one of the higher titre sera. The same technique is used, but incubation is continued for only fifteen inutes, after which the tube is centrifuged slowly for minute before the result is read.

RESULTS

In our experience the risk of false-positive results due o rouleaux formation with albumin-suspended cells has een overrated. We have not encountered trouble rom this factor. When rouleaux are formed they can isually be dispersed by adding an approximately equal olume of saline to the sample of suspension during xamination on the microscope slide.

Of 206 hospital patients Rh tested during the past ourteen months, 29 (14%) gave Rh-negative results with our A.A.A. The different sera gave a surprisingly good conformity of results. In no single instance did cells give a positive agglutination with one serum and frank negative results with another.

From published results (Mollison et al. 1948, Keynes et al. 1949b) the incidence of Rh-negative (cde-cde) persons in the English population appears to lie between 14·78% and 15·10%, giving an average of 14·94%, which is in accordance with our findings with A.A.A. and confirmed the reliability of the method.

DISCUSSION

It is generally accepted that A.A.A. are in the great majority of cases only anti-D specific. It is comparatively rare to find anti-C, anti-E, and anti-c antibodies of this type. On the other hand, S.A.A. against the latter genes, especially anti-C, are not uncommon in association with an incomplete anti-D.

From the practical aspect of the typing of patients about to receive transfusions it is generally considered necessary to examine only for gene D in the recipient's cells. The other genes, C, E, c, d, e, are far less antigenic and very unlikely to cause sensitisation.

It thus seems that A.A.A. are very suitable on theoretical as well as practical grounds for typing patients about to be transfused. An additional advantage is that A.A.A. are more stable as regards heat and storage than S.A.A. (Keynes et al. 1949c).

The possibility that some of our antisera might contain anomalous agglutinins, giving false-positive reactions, is greatly minimised, if not entirely removed, by using two different sera for each test.

SUMMARY AND CONCLUSIONS

With albumin-active antisera (A.A.A.), obtained locally from mothers recently delivered of infants with hæmolytic disease, 206 patients were Rh typed before receiving blood-transfusions.

Sera of this type are abundantly obtainable from natural sources and much greater use should be made of them for the pre-transfusion typing of hospital patients before attempting to produce antisera artificially.

The tube-incubation technique described is rapid and gives results in fifteen minutes. It can readily be mastered by senior members of the staff of hospital pathological laboratories and is more reliable than the Chown capillary-tube technique. The interpretation of results presents no difficulty.

I am indebted to Dr. S. C. Dyke, director of the department of pathology, The Royal Hospital, Wolverhampton, for helpful criticism and the suggestion for clarifying the nomenclature of anti-Rh sera, and to Miss Sheila M. Felton for much technical assistance.

MYOMATA OF THE VERMIFORM APPENDIX

N. N. IOVETZ-TERESHCHENKO
F.R.C.S.
SENIOR SURGICAL REGISTRAR, FULHAM HOSPITAL, LONDON
LATE REGISTRAR, DEPARTMENT OF SURGERY,
POSTGRADUATE MEDICAL SCHOOL OF
LONDON

A tumour originating from unstriated muscle-fibres, the uterine fibroid, is probably the commonest of all tumours in human beings (Whitehouse 1939). In the gastro-intestinal tract, however, tumours of smooth muscle are distinctly uncommon. They may be benign (myomata) or malignant (myosarcomata), and may be composed of unstriped muscle-fibres only (leiomyomata or leiomyosarcomata) or contain a varying proportion of fibrous tissue (leiomyofibromata or leiomyofibrosarcomata).

Myomata of the digestive tract occur most frequently in the stomach (Golden and Stout 1941) and perhaps least frequently in the vermiform appendix. Of the 67 tumours collected by Norment (1932) from 45,000 appendices (0·15%), the 6 tumours found by Shelley (1937) in 2065 consecutive appendicectomies (0·29%), and the 72 tumours reported by Porter and Whelan (1939) among 26,384 appendices (0·28%), not one contained or originated from unstriated muscle-fibres. In these series the mean incidence of tumours of the vermiform appendix of all kinds is only 0·19%, which is considerably less than the usually given incidence of 0·5% (Burton 1947). Stickney (1915) collected 667 reported cases of tumours of the vermiform appendix other than myomata: up to that date 11 myomata had been reported, this being an incidence of 1·62% of all tumours of the vermiform appendix. On this basis the incidence of benign myomata of the vermiform appendix can be estimated at 0·0024% (or approximately 1 in 50,000) of all appendicectomies.

Including the case reported here, only 4 benign leiomyomata have been recorded (table I); in addition, 15 benign leiomyofibromata have also been reported in medical journals (table II). For the sake of completeness, it may be noted that of the 21 reported cases of primary sarcoma of the vermiform appendix, 4 appeared to have originated from or to contain unstriated muscle-fibres (table III).

CASE-REPORT

A housewife, aged 40, was admitted on Jan. 10, 1949, complaining of acute abdominal pain and vomiting for two days. Apart from a laparotomy for, and drainage of, "an abscess of the womb" during the puerperium of her one and only pregnancy 20 years ago, she had not had any illness of note.

Examination.—Some rigidity of the lower abdomen, with guarding in the right iliac fossa, more pronounced than in the left iliac fossa. Pain, most severe just to the right of an ugly, depressed, adherent, left lower paramedian scar. Release tenderness well marked on both sides of the lower end of the scar, where an indefinite small and slightly tender mass could be felt on bimanual examination. Tenderness on the right side on rectal examination.

Operation.—Under general anæsthesia, the adherent left lower paramedian scar was excised, and the peritoneal cavity entered to the left of the midline. The greater omentum was found to be firmly adherent to the lower end of the scar, to the uterus, and by many fine adhesions to the cæcum and colon generally. The adhesions between the omentum and uterus and the colon and omentum were separated in order to obtain access to the pelvis and to the small intestine, but the part of omentum adherent to the anterior abdominal wall at the lower end of the incision was left undisturbed. The right ovary and fallopian tube were normal; the left ovary was rather scarred and adherent to the left cornu of the uterus, but was not removed or in any way interfered with. No obstructed or strangulated bowel was found. A retrocæcal

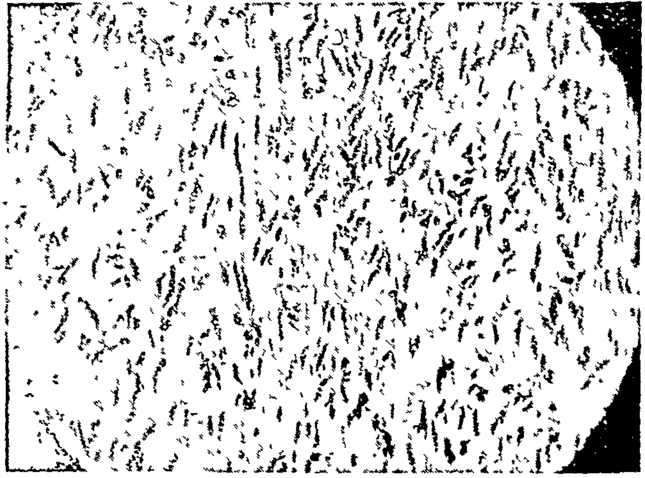

Fig. 1—The leiomyoma, showing spindle-shaped cells forming interlacing bundles. (× 160.)

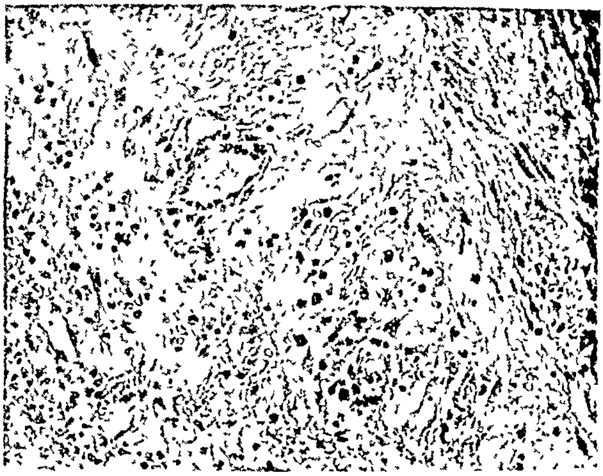

Fig. 2—Edge of the leiomyoma, showing the rough attempt at encapsulation, and also granulation tissue and acute inflammatory cells (× 160.)

vermiform appendix, firmly bound to the cæcum by strong adhesions, was seen to be covered by an abundant fibrinous exudate of apparently recent origin. It also had an expanded and bulbous tip. A retrograde appendicectomy was carried out, a small pocket of pus just proximal to the bulbous tip being discovered and carefully evacuated by means of the sucker. Penicillin-sulphathiazole powder (5 g.) was left behind the cæcum. A large hole in the great omentum was closed with catgut to prevent future mishaps, and the abdominal incision was closed in layers without drainage.

The patient was discharged on Jan. 21, and when seen one month later was very well.

Specimen.—The appendix had a very narrow lumen, completely filled in its distal quarter by a yellowish tumour, which was thought to be an example of the comparatively common carcinoid.

Pathological Report.—The appendix, 4 cm. long, has a small nodule 9 × 7 mm. at tip. Histologically this shows an overgrowth of spindle-shaped cells (exhibiting the staining reaction of smooth muscle with van Gieson's) with elongated nuclei, growing in interlacing bundles (fig. 1) and occasionally forming endothelial lined channels, some of which contain red blood-cells. There is a rough attempt at encapsulation. The adjacent portion of the appendix shows acute suppuration, with loss of lymphoid follicles and some granulation tissue (fig. 2). Mitoses are not common. *Diagnosis:* leiomyoma.

DISCUSSION

Of the 19 reported cases of benign leiomyoma or leiomyofibroma of the vermiform appendix only 1 (Oggioni 1934) was, or indeed could be, diagnosed before

---

* Mentioned by Kelly and Hurdon (1909); all efforts to trace the original report failed; the only article on the appendix by Hayem (1897) contains no reference to any tumours.

operation or autopsy, and in only 2 cases was the tumour palpable per abdomen (in 1 it was in a hernial sac). The sex is stated in only 14 cases (9 females and 5 males), but in at least 3 of the others it was almost certainly female. (A difference in sex-incidence might be explained by the fact that more abdominal operations are performed on women than on men, and consequently the female appendix is more frequently removed.) The youngest patient was aged 20, and the oldest 56.

In 14 of the cases only one tumour was present in the appendix; in 4 cases there was more than one tumour (the largest number in a single specimen being five); and in 1 case no details were given. The smallest tumour was less than 3·5 mm. in diameter; the largest was pear-shaped and measured 9 × 6 cm. One tumour showed calcification similar to that seen in uterine fibroids.

It is possible to consider the smaller of these myomata not as true tumours, but as areas of local hypertrophy of the muscular coats of the appendix (Dr. Bernard Lennox, personal communication); but Maaløe (1908) stated that he had never seen hypertrophy of the appendicular musculature exceeding 2 mm. in thickness.

Lipschütz, with Iglesias, and Vargas (1938–46) described the formation of myomata on the abdominal organs of guineapigs under the influence of stilbœstrol. Whether œstrogens play a part in the ætiology of myomata occurring spontaneously in human beings it is not yet possible to state.

BIBLIOGRAPHICAL NOTES

1. Rosi (1897) refers to a report of an appendicular myoma by Kelly in 1880; no such report could be traced, and it is probable that he was misled and thought, erroneously, that the abdominal rhabdomyoma reported by Kelly (1878) had originated in the appendix.

2. Child (1919) mentions 11 cases of hysterectomy where the vermiform appendix was found to be involved in uterine fibroids. As these cases are not primary tumours of the appendix, they have not been included in this analysis.

3. In an account of a meeting of the Pathological Society of London, Kanthack and Lockwood (1895) are said to have demonstrated a case of "psammoma of the appendix and ovary." No further details being given, it has been assumed that this was a case similar to those reported by Child (1919).

4. *The first authentic case of a tumour* (histology unknown) of the vermiform appendix was reported by von Pommer Esche (1837) and *not* by Merling (1838) as is usually but incorrectly stated. Leichenstern (1876) mentions three cases of "carcinoma of the vermiform appendix," but it is not clear whether these were primary growths or secondary deposits. The first undoubted authentic case of a primary carcinoma of the appendix was reported by Beger (1882) and the first authentic undoubted case of a primary sarcoma of the vermiform appendix was reported by Glazebrook (1895). Gilford (1893) reported a case of "primary sarcoma of the vermiform appendix," but later (1925) he recognised that this had not been a true sarcoma, but was what he calls a "granuloma." Lafforgue (1893) was the first to report a myoma originating in a vermiform appendix.

5. So-called adenomyomata of the appendix are neither true myomata nor primary tumours of the vermiform appendix, and have not been considered here.

SUMMARY

The literature of tumours of the vermiform appendix, and more particularly of myomata (benign and malignant), is briefly reviewed.

The reported cases of leiomyomata, leiomyofibromata, and leiomyosarcomata of the appendix are tabulated, and a new case of leiomyoma is reported.

The findings in the 19 published cases of benign myomata are discussed.

I wish to thank Prof. Ian Aird for permission to publish this case, Dr. A. L. Wells for reporting on the specimen, Mr. E. V. Willmott for the photographs, and Mr. Fernand Perrin, Mr. G. F. Home, Mr. W. J. Bishop, Mr. A. L. Poynter, Mr. E. Cornelius, and Miss D. F. Atkins for their invaluable help in tracking down elusive articles and case-reports.

FATAL POISONING WITH UDOLAC

(DIAMINODIPHENYLSULPHONE)

ROSEMARY DAVIES

M.B. Lond., D.C.H.

LATE PÆDIATRIC REGISTRAR, SOUTH WARWICKSHIRE HOSPITAL GROUP

'UDOLAC,' manufactured by the Imperial Chemical Industries, is a paste containing $33^1/_3$ per cent. of diaminodiphenyl-sulphone; it is used in veterinary practice for the treatment of mastitis in cows. 4 : 4′ diaminodiphenylsulphone is allied clinically and pharmacologically to the sulphonamides. It is more active, but also considerably more toxic, than sulphanilamide (Buttle et al. 1937). In man it may cause methæmoglobinæmia, and its toxic action is due partly to this and partly to a direct toxic action on the brain (Francis 1949). The sulphones have been used in the treatment of leprosy (Rogers 1948), and toxic symptoms have not been encountered with blood levels of less than 2 mg. per 100 ml. Diaminodiphenylsulphone was at one time considered too toxic for use in man, but this is now known not to be the case (Lowe 1950). 'Sulphetrone' is a derivative of 4 : 4′ diaminodiphenylsulphone; it is less toxic because 90% or more is excreted in the fæces (Smith 1949).

The following is an account of the fatal symptoms which arose when a child swallowed about 15 g. of udolac (containing 5 g. of 4 : 4′ diaminodiphenylsulphone).

CASE-RECORD

A girl, aged 22 months, was admitted to hospital at about 9.30 P.M. on July 16, 1949, with a history that she had swallowed some udolac about three hours before. The child had apparently squeezed about half a tube of udolac into her mouth and on to her cheeks and clothes, but her parents

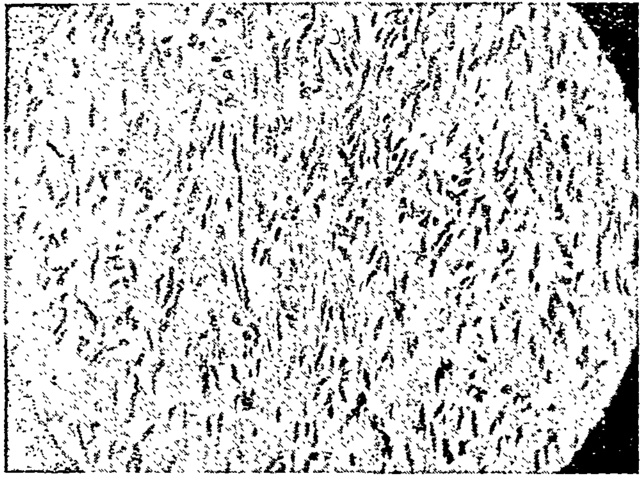

Fig. 1—The leiomyoma, showing spindle-shaped cells forming interlacing bundles. (× 160.)

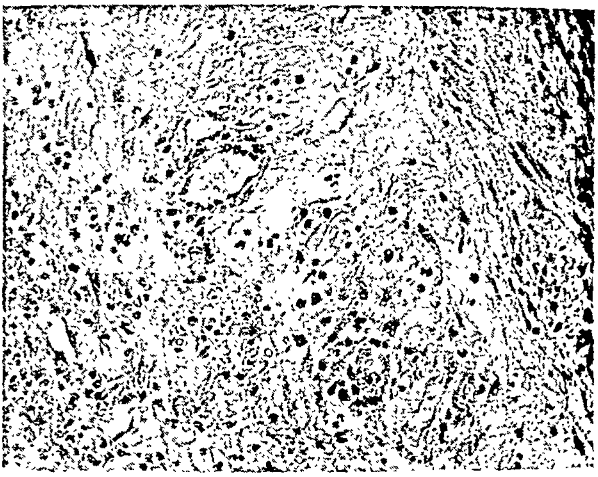

Fig. 2—Edge of the leiomyoma, showing the rough attempt at encapsulation, and also granulation tissue and acute inflammatory cells (× 160.)

vermiform appendix, firmly bound to the cæcum by strong adhesions, was seen to be covered by an abundant fibrinous exudate of apparently recent origin. It also had an expanded and bulbous tip. A retrograde appendicectomy was carried out, a small pocket of pus just proximal to the bulbous tip being discovered and carefully evacuated by means of the sucker. Penicillin-sulphathiazole powder (5 g.) was left behind the cæcum. A large hole in the great omentum was closed with catgut to prevent future mishaps, and the abdominal incision was closed in layers without drainage.

The patient was discharged on Jan. 21, and when seen one month later was very well.

Specimen.—The appendix had a very narrow lumen, completely filled in its distal quarter by a yellowish tumour, which was thought to be an example of the comparatively common carcinoid.

Pathological Report.—The appendix, 4 cm. long, has a small nodule 9 × 7 mm. at tip. Histologically this shows an overgrowth of spindle-shaped cells (exhibiting the staining reaction of smooth muscle with van Gieson's) with elongated nuclei, growing in interlacing bundles (fig. 1) and occasionally forming endothelial lined channels, some of which contain red blood-cells. There is a rough attempt at encapsulation. The adjacent portion of the appendix shows acute suppuration, with loss of lymphoid follicles and some granulation tissue (fig. 2). Mitoses are not common. *Diagnosis :* leiomyoma.

DISCUSSION

Of the 19 reported cases of benign leiomyoma or leiomyofibroma of the vermiform appendix only 1 (Oggioni 1934) was, or indeed could be, diagnosed before

had not realised that she might have swallowed any of it until she became blue and vomited about two and a half hours later. It was estimated that she had swallowed about 5 g. of 4 : 4′ diaminodiphenylsulphone.

On admission she was deeply cyanosed, very restless, and barely conscious.

Treatment and Progress.—She was immediately given a stomach washout, after which she vomited copiously several times—the later vomit contained blood. An intravenous drip transfusion was started in the early hours of July 17, and during that day she was given intravenously 3 pints of 5% glucose in half-strength physiological saline solution. By the evening she was taking fluids well by mouth and the transfusion was stopped. She was very restless, and neither intramuscular phenobarbitone nor intramuscular paraldehyde had any appreciable effect on this. Though placed in an oxygen tent she remained cyanosed, and an abnormal pigment, with a spectrum similar to that of reduced hæmoglobin, was found in the blood. There was no spectroscopic evidence of methæmoglobinæmia. It was thought possible that absorption of the drug from the intestine was continuing; so she was given an enema on July 17 and another on the following day. On July 18 her condition was virtually unchanged, and though she drank fluids readily she took no notice of her surroundings and was still bluish-grey. Her restlessness had lessened, but she had several attacks during which she held her limbs stiffly extended for a minute or two. In the late evening she became unconscious, and crepitations were audible at both lung bases. Her respirations became shallow and irregular, and she died at 4.30 A.M. on July 19, fifty-five hours after swallowing the udolac.

Throughout her illness she passed urine freely, and this contained a trace of albumin and a few red and white cells. Spectroscopy of her urine revealed no abnormal pigment. Her hæmoglobin level remained about 70% and her blood-urea level was 82 mg. per 100 ml. on July 18. The concentration of sulphone in her blood forty-two hours after the udolac had been swallowed was 15 mg. per 100 ml., and in her cerebrospinal fluid 3·3 mg. per 100 ml. Death seemed to be due either to anoxæmia of the anæmic type or to a direct toxic effect of the drug on the vital medullary centres.

Necropsy Findings.—The *brain* was suffused, the cortex especially being greyish pink. On the floor of the left lateral ventricle was an ecchymotic area 1 cm. across, and there were smaller hæmorrhages in the occipital lobes. The cerebellum was hyperæmic, and the brain-stem was slightly congested. Microscopically there were many recent thrombi in the venules of the subcortical white matter. The Virchow-Robin spaces were moderately distended.

The *heart* was externally normal, but the valves were orange in colour, and the papillary muscle of the mitral valve had small ecchymoses upon it. There was œdema of both *lung* bases.

The *gastric mucosa* was smooth, and in the cardia and fundus there were numerous petechiæ. The bowel was collapsed in places. The *liver* was soft, friable, and yellowish brown. The liver cells showed pronounced fatty changes. There were no definite pathological findings in the portal veins, but several central and sublobular veins contained recent thrombi. The *spleen* was small and firm. The malpighian follicles were normal in size, and some showed large germinal centres containing areas of necrosis.

Both *kidneys* were soft, œdematous, and, on a cut section, terra-cotta in colour. The corticomedullary junctions were hyperæmic and the cortex relatively ischæmic. The medullæ were purple and the pyramids prominent. Microscopically the glomeruli showed swelling of the capillary endothelium, and many contained little or no blood. Some loops of the tuft were filled with a shapeless mass of clumped erythrocytes which appeared yellowish red in hæmatoxylin-eosin preparations. Here and there were tiny areas of necrosis, with nuclear débris in the glomeruli, and some amorphous material or a few erythrocytes were sometimes seen in the space of Bowman's capsule. The first convoluted tubules showed swelling and granular and hydropic degeneration of the epithelium. In the loops of Henle the epithelium was disintegrated. The second convoluted tubules, the collecting tubules, and the ducts of Bellini were normal, but some contained red cells.

Post-mortem sulphone concentrations were: blood, 13·5 mg., and urine, 40 mg. per 100 ml.; liver, 16·5 mg., and brain, 9 mg. per 100 g.

DISCUSSION

The main toxic action of udolac in this case seemed to be on the central nervous system, and treatment was therefore confined to eliminating the drug from the body and to combating the anoxæmia and restlessness. The sulphones are excreted in the urine, and this excretion may be increased by giving large quantities of fluid by mouth or intravenously to augment the output of urine. It is impossible to say how much of the restlessness was due to a direct toxic action of the drug on the central nervous system, and how much to anoxia caused by the formation of an abnormal compound of hæmoglobin. The intravenous administration of methylene-blue leads to the disappearance of cyanosis in methæmoglobinæmia (Walliker and Baxter 1949), but in the present case the abnormal pigment was not identified as methæmoglobin. Should the symptoms have been anoxæmic in origin, some relief might have been afforded by increasing the oxygen-carrying capacity of the blood by the transfusion of some fresh blood or perhaps by a replacement transfusion. The technical difficulties of transfusing an extremely restless child are, however, great; and, since the blood-sulphone level was considerably above that known to be toxic, it is doubtful whether such treatment would have been successful.

It is of interest to note that sheep develop nervous symptoms when given sufficiently large doses of sulphone, and Mr. John Francis informs me that no toxic effects were observed in animals receiving 0·1 g. per kg. of body-weight, but of four sheep receiving 0·2 g. per kg. two died and one of the others showed severe toxic symptoms. The toxic action seemed to be exerted on the central nervous system—there was a preliminary period of excitement followed by ataxia, and, in the sheep which recovered after showing these severe toxic symptoms, the symptoms were most acute seven hours after the sulphone had been given, at a time when the blood-sulphone level was 4 mg. per 100 ml.

I wish to thank Prof. J. M. Smellie and Dr. A. I. Cheyne for their help and advice, and Dr. Baar and Dr. Ian Mackenzie for the pathological reports.

ACTIVE SPLINTING FOR RADIAL-NERVE PALSY

K. W. N. PALMER
T.D., L.M.S.S.A., D.Phys.Med.
DIRECTOR OF PHYSICAL MEDICINE, DURHAM AND GATESHEAD HOSPITAL GROUPS

THE loss of normal muscle tone and active movement in the extensors of the wrist and fingers as a result of peripheral nerve injury is a severe handicap. The object of the splint described here is to restore conditions to as near normal as possible during the period of regeneration after such an injury.

RATIONALE

If the right hand is affected, or the left hand in left-handed people, the patient's whole life is altered. Even when there is no movement the hand feels awkward. The cortical sensory pattern received from muscle, tendon, and joint sense is strange and unbalanced. Attempted movements are uncoordinated, and it is impossible to stabilise the wrist. If this state persists for a considerable time the joints become stiff, the ligaments contract, and the unopposed antagonists

become shorter. As a result of disuse the patient tends to forget how to use the hand. There is a feeling of frustration, more especially if the patient is a highly skilled technician. Rigid splinting produces a rigid hand, which in addition becomes atrophied. The hand needs movement if it is to regain normal function.

The type of active splint described here was designed to hold the hand in the position of function with a normal balance of tone reproduced by elastic. The importance of this becomes obvious when, after minor adjustments in the angle of pull and tension, the patient says " It feels right," " I don't realise there is anything wrong with my hand." When this happens, something approaching the normal sensory cortical pattern has been restored, and a striking change will then be noted in the patient's willingness to use the hand.

It is physiological that the hand should be kept in use —normal use so far as possible—until the nerve has recovered (where this is the expected result from treatment). The nutrition of the whole forearm and hand then remains almost normal. The skin is very different in appearance, temperature, and texture from that of a hand which has been held in a rigid splint. The venous and lymphatic return is maintained, and the denervated muscles are exercised by active splinting and daily interrupted galvanism. The degree of muscle wasting is much reduced by this treatment.

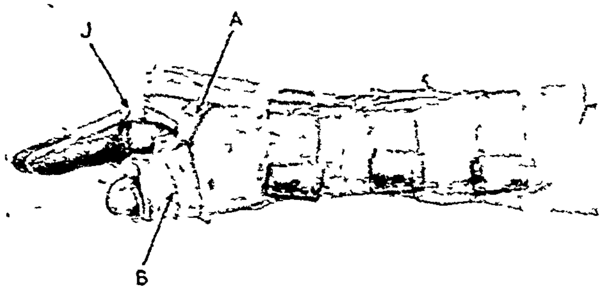

Fig. 1—Splint with wrist in dorsiflexion and fingers extended at metacarpophalangeal joints.

THE SPLINT

The splint is made of ' Perspex ' moulded from a plaster cast taken with the arm and hand in the position of function. In most cases this is the writing position, in which the heads of the metacarpal bones form a conspicuous arch, the wrist is dorsiflexed, and the forearm is partly pronated. In the case illustrated the patient's skin sensation was impaired and it was decided to allow room for padding with elephant felt, but with normal skin the perspex can be applied direct, which is more convenient since the whole splint can be washed.

Extension of the wrist is maintained by a strip of elastic $1^{1}/_{2}$ in. wide padded with felt $^{1}/_{4}$ in. thick passing round the splint and across the distal part of the palm (fig. 1A). This allows a small range of flexion against resistance, which is useful in writing.

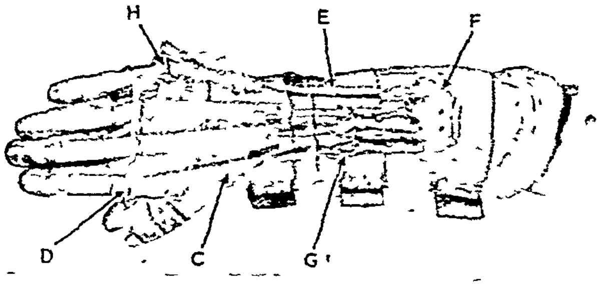

Fig. 2—Splint showing tendons, slots, extended thumb, and elastic with adjustable toggles.

Extension of the thumb is maintained by a similar piece of elastic (fig. 1B). The perspex behind the thumb holds it in full extension at right angles to the palm. This allows flexion against resistance and a limited range of adduction and abduction.

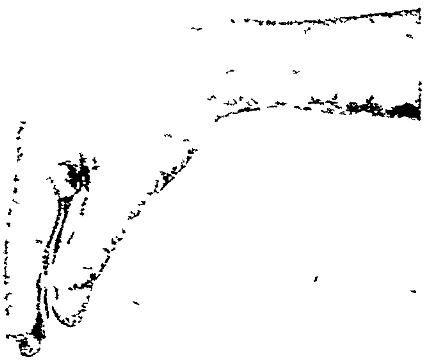

Fig. 3—Unsupported hand and wrist.

Extension of the metacarpophalangeal joints is produced by plastic "tendons" $^{1}/_{2}$ in. wide (fig. 2C) which pass through oblique slots (fig. 2D) in the perspex. These are attached to elastic $^{1}/_{4}$ in. wide (fig. 2E) which passes through a slot in a bridge (fig. 2F) placed in line with the lateral epicondyle.

Small toggles (fig. 2G) attached to the elastic allow the tension to be varied easily. When the hand is not in use, it becomes less readily tired if the tension is reduced.

The angle and position of the slots through which the tendons pass are important. With the fingers out straight the slot for the plastic "tendon" of the fifth finger must be close to the head of the fifth metacarpal but medial to it. Each slot should slope in a plane at right angles to a line passing through the corresponding metacarpal head and the radial styloid process. If this is not done the tendons pull obliquely and cut into the fingers. The distal ends of the tendons are fastened into the fingers of a thin glove, the position of pull being from near the head of the proximal phalanx (fig. 1J). The pull should not be taken from the tip of the terminal phalanx, which is unstable and easily overextended.

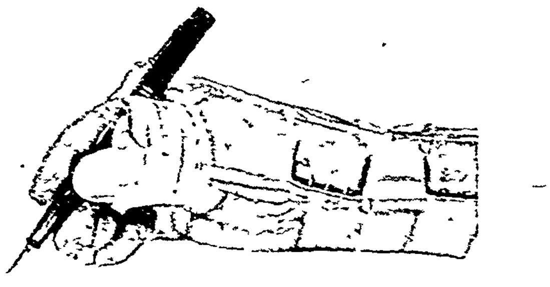

Fig. 4—Splinted hand in writing position, showing ample movement possible with thumb.

The splint is secured by three webbing straps with the buckles resting on the perspex. The tendency of the splint to ride forward is prevented by dorsiflexion of the wrist and careful moulding round the wrist. A large hole or depression should be made in the splint for the head of the ulna, to relieve pressure.

RESULTS

In the case illustrated the patient had had a useless hand (fig. 3) for two months. The radial-nerve palsy was the result of a pathological fracture of the humerus. Three days after the splint was applied he was back at work and signed over 300 documents on his first day (fig. 4). The psychological effect of this was great. The patient has time off from work for daily treatment to

had not realised that she might have swallowed any of it until she became blue and vomited about two and a half hours later. It was estimated that she had swallowed about 5 g. of 4 : 4′ diaminodiphenylsulphone.

On admission she was deeply cyanosed, very restless, and barely conscious.

Treatment and Progress.—She was immediately given a stomach washout, after which she vomited copiously several times—the later vomit contained blood. An intravenous drip transfusion was started in the early hours of July 17, and during that day she was given intravenously 3 pints of 5% glucose in half-strength physiological saline solution. By the evening she was taking fluids well by mouth and the transfusion was stopped. She was very restless, and neither intramuscular phenobarbitone nor intramuscular paraldehyde had any appreciable effect on this. Though placed in an oxygen tent she remained cyanosed, and an abnormal pigment, with a spectrum similar to that of reduced hæmoglobin, was found in the blood. There was no spectroscopic evidence of methæmoglobinæmia. It was thought possible that absorption of the drug from the intestine was continuing; so she was given an enema on July 17 and another on the following day. On July 18 her condition was virtually unchanged, and though she drank fluids readily she took no notice of her surroundings and was still bluish-grey. Her restlessness had lessened, but she had several attacks during which she held her limbs stiffly extended for a minute or two. In the late evening she became unconscious, and crepitations were audible at both lung bases. Her respirations became shallow and irregular, and she died at 4.30 A.M. on July 19, fifty-five hours after swallowing the udolac.

Throughout her illness she passed urine freely, and this contained a trace of albumin and a few red and white cells. Spectroscopy of her urine revealed no abnormal pigment. Her hæmoglobin level remained about 70% and her blood-urea level was 82 mg. per 100 ml. on July 18. The concentration of sulphone in her blood forty-two hours after the udolac had been swallowed was 15 mg. per 100 ml., and in her cerebrospinal fluid 3·3 mg. per 100 ml. Death seemed to be due either to anoxæmia of the anæmic type or to a direct toxic effect of the drug on the vital medullary centres.

Necropsy Findings.—The *brain* was suffused, the cortex especially being greyish pink. On the floor of the left lateral ventricle was an ecchymotic area 1 cm. across, and there were smaller hæmorrhages in the occipital lobes. The cerebellum was hyperæmic, and the brain-stem was slightly congested. Microscopically there were many recent thrombi in the venules of the subcortical white matter. The Virchow-Robin spaces were moderately distended.

The *heart* was externally normal, but the valves were orange in colour, and the papillary muscle of the mitral valve had small ecchymoses upon it. There was œdema of both *lung* bases.

The *gastric mucosa* was smooth, and in the cardia and fundus there were numerous petechiæ. The bowel was collapsed in places. The *liver* was soft, friable, and yellowish brown. The liver cells showed pronounced fatty changes. There were no definite pathological findings in the portal veins, but several central and sublobular veins contained recent thrombi. The *spleen* was small and firm. The malpighian follicles were normal in size, and some showed large germinal centres containing areas of necrosis.

Both *kidneys* were soft, œdematous, and, on a cut section, terra-cotta in colour. The corticomedullary junctions were hyperæmic and the cortex relatively ischæmic. The medullæ were purple and the pyramids prominent. Microscopically the glomeruli showed swelling of the capillary endothelium, and many contained little or no blood. Some loops of the tuft were filled with a shapeless mass of clumped erythrocytes which appeared yellowish red in hæmatoxylin-eosin preparations. Here and there were tiny areas of necrosis, with nuclear débris in the glomeruli, and some amorphous material or a few erythrocytes were sometimes seen in the space of Bowman's capsule. The first convoluted tubules showed swelling and granular and hydropic degeneration of the epithelium. In the loops of Henle the epithelium was disintegrated. The second convoluted tubules, the collecting tubules, and the ducts of Bellini were normal, but some contained red cells.

Post-mortem sulphone concentrations were: blood, 13·5 mg., and urine, 40 mg. per 100 ml.; liver, 16·5 mg., and brain, 9 mg. per 100 g.

DISCUSSION

The main toxic action of udolac in this case seemed to be on the central nervous system, and treatment was therefore confined to eliminating the drug from the body and to combating the anoxæmia and restlessness. The sulphones are excreted in the urine, and this excretion may be increased by giving large quantities of fluid by mouth or intravenously to augment the output of urine. It is impossible to say how much of the restlessness was due to a direct toxic action of the drug on the central nervous system, and how much to anoxia caused by the formation of an abnormal compound of hæmoglobin. The intravenous administration of methylene-blue leads to the disappearance of cyanosis in methæmoglobinæmia (Walliker and Baxter 1949), but in the present case the abnormal pigment was not identified as methæmoglobin. Should the symptoms have been anoxæmic in origin, some relief might have been afforded by increasing the oxygen-carrying capacity of the blood by the transfusion of some fresh blood or perhaps by a replacement transfusion. The technical difficulties of transfusing an extremely restless child are, however, great; and, since the blood-sulphone level was considerably above that known to be toxic, it is doubtful whether such treatment would have been successful.

It is of interest to note that sheep develop nervous symptoms when given sufficiently large doses of sulphone, and Mr. John Francis informs me that no toxic effects were observed in animals receiving 0·1 g. per kg. of body-weight, but of four sheep receiving 0·2 g. per kg. two died and one of the others showed severe toxic symptoms. The toxic action seemed to be exerted on the central nervous system—there was a preliminary period of excitement followed by ataxia, and, in the sheep which recovered after showing these severe toxic symptoms, the symptoms were most acute seven hours after the sulphone had been given, at a time when the blood-sulphone level was 4 mg. per 100 ml.

ACTIVE SPLINTING FOR RADIAL-NERVE PALSY

K. W. N. PALMER
T.D., L.M.S.S.A., D.Phys.Med.
DIRECTOR OF PHYSICAL MEDICINE, DURHAM AND GATESHEAD HOSPITAL GROUPS

THE loss of normal muscle tone and active movement in the extensors of the wrist and fingers as a result of peripheral nerve injury is a severe handicap. The object of the splint described here is to restore conditions to as near normal as possible during the period of regeneration after such an injury.

RATIONALE

If the right hand is affected, or the left hand in left-handed people, the patient's whole life is altered. Even when there is no movement the hand feels awkward. The cortical sensory pattern received from muscle, tendon, and joint sense is strange and unbalanced. Attempted movements are uncoördinated, and it is impossible to stabilise the wrist. If this state persists for a considerable time the joints become stiff, the ligaments contract, and the unopposed antagonists

become shorter. As a result of disuse the patient tends to forget how to use the hand. There is a feeling of frustration, more especially if the patient is a highly skilled technician. Rigid splinting produces a rigid hand, which in addition becomes atrophied. The hand needs movement if it is to regain normal function.

The type of active splint described here was designed to hold the hand in the position of function with a normal balance of tone reproduced by elastic. The importance of this becomes obvious when, after minor adjustments in the angle of pull and tension, the patient says " It feels right," " I don't realise there is anything *wrong with my hand." When this happens, something* approaching the normal sensory cortical pattern has been restored, and a striking change will then be noted in the patient's willingness to use the hand.

It is physiological that the hand should be kept in use—normal use so far as possible—until the nerve has recovered (where this is the expected result from treatment). The nutrition of the whole forearm and hand then remains almost normal. The skin is very different in appearance, temperature, and texture from that of a hand which has been held in a rigid splint. The venous and lymphatic return is maintained, and the denervated muscles are exercised by active splinting and daily interrupted galvanism. The degree of muscle wasting is much reduced by this treatment.

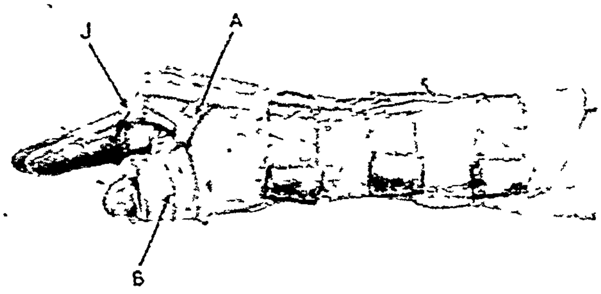

Fig. 1—Splint with wrist in dorsiflexion and fingers extended at metacarpophalangeal joints.

THE SPLINT

The splint is made of 'Perspex' moulded from a plaster cast taken with the arm and hand in the position of function. In most cases this is the writing position, in which the heads of the metacarpal bones form a conspicuous arch, the wrist is dorsiflexed, and the forearm is partly pronated. In the case illustrated the patient's skin sensation was impaired and it was decided to allow room for padding with elephant felt, but with normal skin the perspex can be applied direct, which is more convenient since the whole splint can be washed.

Extension of the wrist is maintained by a strip of elastic $1\frac{1}{2}$ in. wide *padded with felt* $\frac{1}{4}$ *in. thick* passing round the splint and across the distal part of the palm (fig. 1A). This allows a small range of flexion against resistance, which is useful in writing.

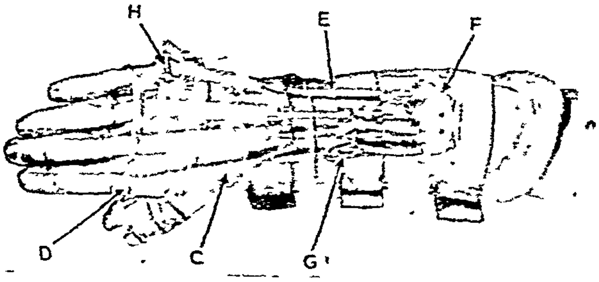

Fig. 2—Splint showing tendons, slots, extended thumb, and elastic with adjustable toggles.

Extension of the thumb is maintained by a similar piece of elastic *(fig. 1B). The* perspex behind the thumb holds it in full extension at right angles to the palm. This allows flexion against resistance and a limited range of adduction and abduction.

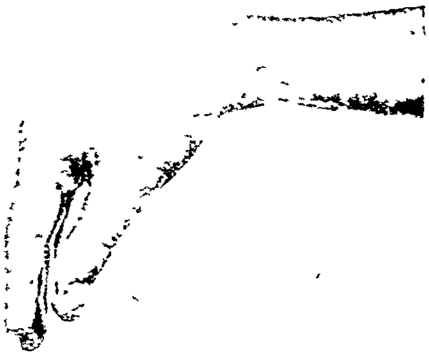

Fig. 3—Unsupported hand and wrist.

Extension of the metacarpophalangeal joints is produced by plastic "tendons" $\frac{1}{2}$ in. wide (fig. 2C) which pass through oblique slots (fig. 2D) in the perspex. These are attached to elastic $\frac{1}{4}$ in. wide (fig. 2E) which passes through a slot in a bridge (fig. 2F) placed in line with the lateral epicondyle.

Small toggles (fig. 2G) attached to the elastic allow the tension to be varied easily. When the hand is not in use, it becomes less readily tired if the tension is reduced.

The angle and position of the slots through which the tendons pass are *important.* With the fingers out straight the slot for the plastic "tendon" of the fifth finger must be close to the head of the fifth metacarpal but medial to it. Each slot should slope in a plane at right angles to a line passing through the corresponding metacarpal head and the radial styloid process. If this is not done the tendons pull obliquely and cut into the fingers. *The distal ends of the tendons* are fastened into the fingers of a thin glove, the position of pull being from near the head of the proximal phalanx (fig. 1J). The pull should not be taken from the tip of the terminal phalanx, which is unstable and easily overextended.

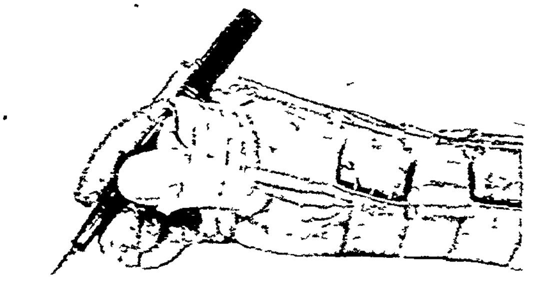

Fig. 4—Splinted hand in writing position, showing ample movement possible with thumb.

The splint is secured by three webbing straps with the buckles resting on the perspex. The tendency of the splint to ride forward is prevented by dorsiflexion of the wrist and careful moulding round the wrist. A large hole or depression should be made in the splint for the head of the ulna, to relieve pressure.

RESULTS

In the case illustrated the patient had had a useless hand (fig. 3) for two months. The radial-nerve palsy was the result of a pathological fracture of the humerus. Three days after the splint was applied he was back at work and signed over 300 documents on his first day (fig. 4). The *psychological effect* of this was great. ACTIVE SPLINTING FOR RADIAL-NERVE PALSY

K. W. N. PALMER
T.D., L.M.S.S.A., D.Phys.Med.
DIRECTOR OF PHYSICAL MEDICINE, DURHAM AND GATESHEAD HOSPITAL GROUPS

THE loss of normal muscle tone and active movement in the extensors of the wrist and fingers as a result of peripheral nerve injury is a severe handicap. The object of the splint described here is to restore conditions to as near normal as possible during the period of regeneration after such an injury.

RATIONALE

If the right hand is affected, or the left hand in left-handed people, the patient's whole life is altered. Even when there is no movement the hand feels awkward. The cortical sensory pattern received from muscle, tendon, and joint sense is strange and unbalanced. Attempted movements are uncoördinated, and it is impossible to stabilise the wrist. If this state persists for a considerable time the joints become stiff, the ligaments contract, and the unopposed antagonists

become shorter. As a result of disuse the patient tends to forget how to use the hand. There is a feeling of frustration, more especially if the patient is a highly skilled technician. Rigid splinting produces a rigid hand, which in addition becomes atrophied. The hand needs movement if it is to regain normal function.

The type of active splint described here was designed to hold the hand in the position of function with a normal balance of tone reproduced by elastic. The importance of this becomes obvious when, after minor adjustments in the angle of pull and tension, the patient says "It feels right," "I don't realise there is anything wrong with my hand." When this happens, something approaching the normal sensory cortical pattern has been restored, and a striking change will then be noted in the patient's willingness to use the hand.

It is physiological that the hand should be kept in use —normal use so far as possible—until the nerve has recovered (where this is the expected result from treatment). The nutrition of the whole forearm and hand then remains almost normal. The skin is very different in appearance, temperature, and texture from that of a hand which has been held in a rigid splint. The venous and lymphatic return is maintained, and the denervated muscles are exercised by active splinting and daily interrupted galvanism. The degree of muscle wasting is much reduced by this treatment.

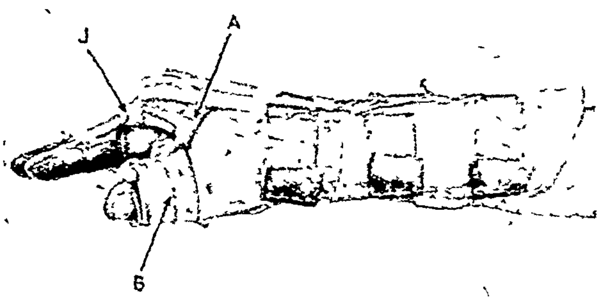

Fig. 1—Splint with wrist in dorsiflexion and fingers extended at metacarpophalangeal joints.

THE SPLINT

The splint is made of 'Perspex' moulded from a plaster cast taken with the arm and hand in the position of function. In most cases this is the writing position, in which the heads of the metacarpal bones form a conspicuous arch, the wrist is dorsiflexed, and the forearm is partly pronated. In the case illustrated the patient's skin sensation was impaired and it was decided to allow room for padding with elephant felt, but with normal skin the perspex can be applied direct, which is more convenient since the whole splint can be washed.

Extension of the wrist is maintained by a strip of elastic 1$^1/_2$ in. wide padded with felt $^1/_4$ in. thick passing round the splint and across the distal part of the palm (fig. 1A). This allows a small range of flexion against resistance, which is useful in writing.

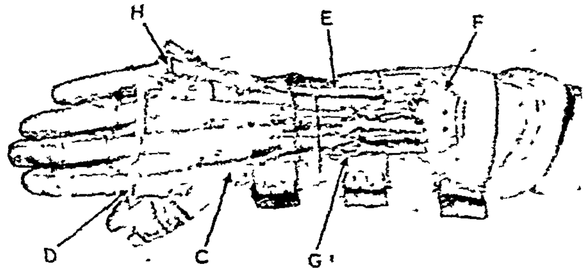

Fig. 2—Splint showing tendons, slots, extended thumb, and elastic with adjustable toggles.

Extension of the thumb is maintained by a similar piece of elastic (fig. 1B). The perspex behind the thumb holds it in full extension at right angles to the palm. This allows flexion against resistance and a limited range of adduction and abduction.

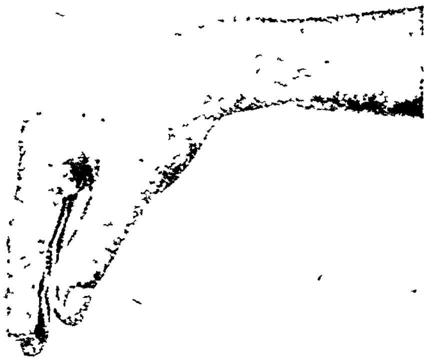

Fig. 3—Unsupported hand and wrist.

Extension of the metacarpophalangeal joints is produced by plastic "tendons" $^1/_2$ in. wide (fig. 2C) which pass through oblique slots (fig. 2D) in the perspex. These are attached to elastic $^1/_4$ in. wide (fig. 2E) which passes through a slot in a bridge (fig. 2F) placed in line with the lateral epicondyle.

Small toggles (fig. 2G) attached to the elastic allow the tension to be varied easily. When the hand is not in use, it becomes less readily tired if the tension is reduced.

The angle and position of the slots through which the tendons pass are important. With the fingers out straight the slot for the plastic "tendon" of the fifth finger must be close to the head of the fifth metacarpal but medial to it. Each slot should slope in a plane at right angles to a line passing through the corresponding metacarpal head and the radial styloid process. If this is not done the tendons pull obliquely and cut into the fingers. The distal ends of the tendons are fastened into the fingers of a thin glove, the position of pull being from near the head of the proximal phalanx (fig. 1J). The pull should not be taken from the tip of the terminal phalanx, which is unstable and easily overextended.

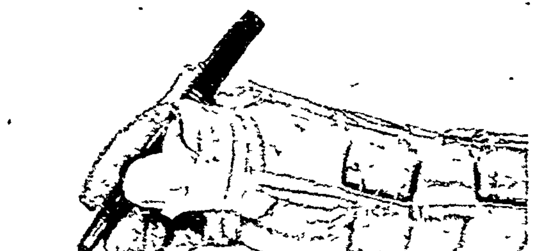

Fig. 4—Splinted hand in writing position, showing ample movement possible with thumb.

The splint is secured by three webbing straps with the buckles resting on the perspex. The tendency of the splint to ride forward is prevented by dorsiflexion of the wrist and careful moulding round the wrist. A large hole or depression should be made in the splint for the head of the ulna, to relieve pressure.

RESULTS

In the case illustrated the patient had had a useless hand (fig. 3) for two months. The radial-nerve palsy was the result of a pathological fracture of the humerus. Three days after the splint was applied he was back at work and signed over 300 documents on his first day (fig. 4). The psychological effect of this was great. The patient has time off from work for daily treatment to the paralysed muscles, which show complete reaction of degeneration, with fibrillation action potentials and no voluntary action potentials on electromyography.

CONCLUSION

As a principle the aim should be to produce normal or as near normal action as possible in a paralysed limb. The tendency to adapt a machine to fit a patient's disability usually produces abnormal and clumsy movement. Active splinting "feels right" and enables the patient to reproduce something very like the existing coördinated movements without a great effort of concentration.

I am indebted to Mr. H. J. B. Atkins, F.R.C.S., director of surgery, Guy's Hospital, for permission to photograph this patient, and to Prof. James Whillis, M.D., of Guy's Hospital Medical School, for advice on the anatomy of the hand.

LIVER CHOLINE-ESTERASE IN MALNOURISHED INFANTS

JOHN WATERLOW
M.D.
MEMBER OF HUMAN NUTRITION RESEARCH UNIT, MEDICAL RESEARCH COUNCIL, FIELD RESEARCH STATION, FAJARA, GAMBIA, BRITISH WEST AFRICA

A REDUCTION in total choline-esterase of the serum was found by McCance and his colleagues (1948) in undernourished Germans. It has also been known for some years that plasma or serum esterase is reduced in liver disease, particularly cirrhosis. Many recent papers have described the high incidence of liver disease in the tropics, in infants and children as well as in adults. There is strong evidence that this liver damage may, in part at least, be caused by malnutrition. A logical link between these two effects attributed to malnutrition—liver damage and a low serum-esterase level—would be a reduction in the esterase activity of the liver cell. Preliminary findings in malnourished African infants are in agreement with this expectation: a low esterase activity of the liver has been found, accompanied by histological evidence of early liver damage.

METHODS AND FINDINGS

In 20 infants admitted to the research ward at Fajara with malnutrition the average plasma-esterase concentration was 22·5 units (1 unit = the amount of enzyme liberating 1 c.mm. of CO_2 per ml. of plasma per minute). This is lower than in the lowest group described by McCance et al., in which the mean level was 29 units.

In 2 of these babies, both of whom had œdema with hypoproteinæmia, we have measured the esterase activity of the liver and studied its histology. Liver tissue was obtained by aspiration biopsy through the pleural sac by the method of Iversen and Roholm (1939). A first biopsy was done soon after admission, and a second four to five weeks later. In the interval the babies were fed on millet pap and cow's milk. Case 1, which was 2 years old, took an average of 37 oz. of milk a day. Case 2, which was 15 months old, was still being breast-fed, and in addition took 31 oz. of cow's milk daily.

Enzyme Activity

All enzyme measurements, both on liver and plasma, were made by the Cartesian diver microgasometric technique of Linderstrom-Lang and Holter (1943), with modifications described by Waterlow and Borrow (1949). Esterase was measured by the liberation of CO_2 from bicarbonate in divers filled with 5% CO_2 and 95% O_2. The substrate was 2·5% acetylcholine. About 2 mg. fresh weight of liver was weighed on a quartz-fibre balance and homogenised in 23 c.mm. of Ringer-bicarbonate solution; 1·5 c.mm. of homogenate was used for each estimation. The mean difference between duplicate measurements on the same homogenate was 5·5%. Cytochrome oxidase was measured with ascorbate as substrate at two levels of tissue concentration. Lactic-dehydrogenase activity was measured in case 2 by the oxygen-uptake in the presence of lactate, methylene-blue, cyanide, and cozymase. All the liver-biopsy findings are expressed as O_2-uptake or CO_2-output per mg. dry weight per hour.

The values found for liver esterase and for plasma protein and plasma esterase are shown in the accompanying table. In both babies the initial level of liver esterase was low, compared with 4 controls, but there was an increase of more than 100% after the period of feeding on a high milk diet. Case 2 was removed from hospital by its mother before recovery was complete, as judged both by clinical standards and by the figures for plasma and liver esterase.

In spite of the large sampling and other errors involved in these measurements, the increase in liver esterase activity between the initial and final biopsies is thought to be significant. Comparison with the results for the other enzyme systems shows that the low level on admission was not a non-specific effect, caused, for instance, by dilution with fat. The low cytochrome-oxidase activity in the first specimen of case 2 is of doubtful significance. The errors in this assay were relatively large, because the measurement had to be made at two different tissue concentrations. The fall in lactic-dehydrogenase activity has been confirmed in 2 other cases. It would seem that this enzyme is relatively stable under conditions of malnutrition.

Histology

The microscopical appearances of the samples of liver were substantially the same in the two babies. There was a small amount of fat in large droplets, irregularly distributed at the periphery of the lobules. The Kupffer cells and portal tracts contained heavy deposits of malarial pigment. In and round the portal tracts were cells resembling fibroblasts. Silver-impregnation showed an outgrowth of fine and moderately thick fibres from the edges of the tracts into the parenchyma, in places forming a network round small groups of liver cells.

LIVER-BIOPSY AND PLASMA FINDINGS IN 2 MALNOURISHED AFRICAN BABIES, ON ADMISSION AND AFTER FOUR TO FIVE WEEKS ON HIGH-MILK DIET

Subjects	In liver (c.mm./mg./hr.)			In plasma	
	Esterase (CO_2-output)	Cytochrome oxidase (O_2-uptake)	Lactic dehydrogenase (O_2-uptake)	Total protein (g. per 100 ml.)	Esterase (units)
Case 1					
Initial ..	4·0	18·1	—	4·45	11·7
Final ..	8·85	16·8	—	7·1	58·7
Case 2					
Initial ..	2·3	8·3	8·7	4·7	23·2
Final ..	5·85	12·8	5·1	6·95	44·7
Four controls					
Mean ..	8·8	14·3	5·4	—	—
Range ..	7·4–13·2	10·6–17·0	4·9–6·4	—	—

In case 2 only a small amount of tissue was obtained at the second biopsy, and none was set aside for histological examination. In case 1 the most striking change between the initial and final biopsies was the increase in size of the liver cells. In sections from the first biopsy 260 hepatic cell nuclei were counted in a standard area, compared with 192 in the second, which indicates a decrease of some 35% in the volume of the liver cells. This decrease is of the same order as the loss of labile cytoplasm demonstrated by Kosterlitz (1944) in protein-starved rats.

COMMENT

Miller (1948), Schultz (1949), and Williams and Elvehjem (1949) have found that in animals during starvation or feeding on a diet low in available amino-acids here is a selective loss of cathepsin and of xanthine oxidase from the liver. The results of the present study suggest that the so-called "pseudo"-choline-esterase should be added to this list. Since the liver cells are reduced in size, the reduction in enzyme concentration per cell is greater than appears from the figures based on dry weight. In case 1 the relative activity per cell can be roughly computed from the results of the nuclear counts given above. Such a calculation shows that between the initial and final biopsies the esterase activity per cell increased $3^1/_2$ times. This fall in the esterase activity of the cell in malnutrition is interesting, in view of the possibility (Lipmann 1946) that esterase may be concerned with the acetylation of amino-acids as a stage in the synthesis of protein.

CLEANLINESS OF SURGEONS' APRONS

D. C. CORRY

M.D. Lond., F.R.C.S.

SURGEON, RADCLIFFE INFIRMARY, OXFORD

IN most operating-theatres the surgeon and his assistants, having changed into freshly laundered theatre clothes, put on surgeons' aprons and work through the list.

The surgeon's apron has always reminded me of the frock-coat of the earlier surgeons—something rather dirty. When I anticipate a dry operation I have the apron taken off after scrubbing up. If I feel I am likely to need its protection I have the splashes on the apron from scrubbing up dried by a towel, because I feel that any organisms from the apron will be able to penetrate a wet operating-gown.

The method of cleaning aprons at the Radcliffe Infirmary was to take them to the sink-room after the surgeon had finished using them. The aprons were then washed by porters with soap and water, using a scrubbing-brush, and subsequently soaked in 2% lysol for a few minutes. They were then rinsed in water and hung out in the open to dry before being returned to the surgeons' room for further use.

To test the surgical cleanliness of the aprons, cultures were taken early one morning last summer from six aprons waiting to be used in the surgeons' room. The aprons were swabbed with a throat-swab moistened in sterile ampoules of distilled water, and making a Z-shaped wipe once over an area of about a square inch. There was a heavy growth from all the swabs. The variety of organisms cultured increased from the neck-band to the lower part of the apron:

Neck-band: *Staphylococcus aureus*.

Front upper part of apron: *Proteus*.

Middle lower part of apron: *Staph. aureus* and *Staph. albus*.

Bottom part of apron: *Staph. aureus*, *Staph. albus*, *Proteus*, and aerobic spore-bearers.

Inner surface of apron: micrococci.

From the boots were grown *Staph. aureus*, *Staph. albus*, and aerobic spore-bearers.

The matter was reported to the standing health and hygiene committee of the infirmary. On the advice of Dr. R. L. Vollum the length of time the aprons are soaked in 2% lysol was increased to an hour. Care is taken by the porters to see that the whole apron is covered by the lysol; otherwise the cleansing routine remains the same.

During the past three months, on about the first day of the month, six swabs have been taken from aprons waiting to be used. The only positive culture has been slight growth of *Staph. albus* from a waist-band on one occasion.

My thanks are due to Mr. Victor Pearse, F.R.C.S., for taking the swabs, and to Mr. R. L. Vollum, D.PHIL., for bacteriological advice and help.

Reviews of Books

Penicillin

Its Practical Application. (2nd ed.) Editor: Sir ALEXANDER FLEMING, F.R.C.P., F.R.C.S., F.R.S. London: Butterworth. 1950. Pp. 491. 30s.

THIS is the second edition of a book which has already proved its value. It is not a continuous textbook but a series of independent contributions made by many specialists, each showing how penicillin can best be used in the field of medicine on which he is an authority. During the three years since this book first appeared penicillin has become so plentiful as to be available for all needs, even trivial ones, and experience has been gained so that treatment has now become more standardised. In addition, commercial penicillin has become purer. For all practical purposes, penicillin of good quality is no longer toxic, and all the toxic effects recorded in man have been of a minor nature; on the other hand various allergic reactions to repeated injections have been described, chiefly urticaria and erythema-vesicular eruptions.

The first part of the book has general chapters about the chemistry, manufacture, pharmacology, and administration of penicillin. Then there are chapters on the application of penicillin to special sites and conditions, in which its uses in surgery are particularly well represented. Other chapters cover the use of penicillin in general practice, and also in dentistry and in veterinary practice. There is a chapter on streptomycin and brief notes on 'Chloromycetin' and 'Aureomycin.' Throughout, the book is written mainly for the practising doctor, whether in general practice or in one of the specialties. It is convenient in size and format; and well deserves recommendation.

Brucellosis (Undulant Fever)

Clinical and Subclinical. (2nd ed.) HAROLD J. HARRIS, M.D., F.A.C.P., with the assistance of BLANCHE L. STEVENSON, R.N. New York: Paul B. Hoeber. 1950. Pp. 617. $10.

ALL students of undulant fever will be grateful to Dr. H. J. Harris for the new edition of this valuable work. It includes information culled from 742 papers by almost as many authors, and from his own observations of about 700 cases between 1932 and 1950. The formidable nature of the task is illustrated by the fact that in spite of his efforts some important contributions have escaped attention. Thus his otherwise admirable exposition of the history of his subject does not mention the case of undulant fever in Rhodesia in which Bevan[1] found an agglutination titre of 1 in 200 for *Brucella abortus*, suggesting that the infection was contracted from cattle. Similarly overlooked is Orpen's[2] evidence in 1924 that in Rhodesia *abortus* and not *melitensis* is the cause of undulant fever.

Dr. Harris's critical examination of the known facts is refreshing, and nowhere is his scientific approach more welcome than in the section on so-called "chronic brucellosis." The very definition of this condition raises difficult questions which have caused some to doubt its existence. The evidence he gives of the survival of brucella in milk products under laboratory conditions (for instance, "butter yielded *Brucella abortus* after storage at 8°C for one hundred and forty-two days") tends perhaps to suggest a more serious danger than really exists; but his comments on interhuman infection are admirably critical: e.g., "It seems all but impossible to evaluate human transmission since no individual can be proved to be uninfected prior to the suspected human contact, so inapparent and obscure may have been a previously acquired infection." Only two short paragraphs are devoted to the interesting question of sex-incidence, though a table in another section, showing mortality-rates in the United States for the years 1940–45, brings out the large preponderance of males over females. This preponderance, not only in mortality but also in incidence, has been reported from many countries including our own.[3]

---

[1] Bevan, L. E. W. *Trans. R. Soc. trop. Med. Hyg.* 1921, **15**, 215.

[2] Orpen, L. J. J. *Ibid*, 1924, **17**, 521.

Almost every aspect of this obscure but fascinating disease has been considered; and the many fine illustrations include coloured photographs of skin rashes and intradermal reactions. Dr. Harris's book is an indispensable reference work. We condole with him on the misfortune that this edition appeared just too soon to include reference to the astonishing, though not yet critically evaluated, results of medication with 'Aureomycin' and chloramphenicol.

Lectures on Medicine to Nurses

A. E. Clark-Kennedy, M.D., F.R.C.P., dean of the medical school, London Hospital. Edinburgh: E. & S. Livingstone. 1950. Pp. 282. 15*s.* 6*d.*

Dr. Clark-Kennedy's lectures for nurses are written in his own style with all his customary skill and originality. The lectures are designed to give nurses an outlook on medicine which will enable them to think out what is happening when nursing sick patients. He has not used the method of the textbook, which—since he hates catalogues—he describes as "frightfully dull," but has preferred to try to make his audience think for themselves. His teaching is largely by analogy, and ranges from elephants in Piccadilly to motor-cars, and from the London blitz to British Railways. The light friendly spirit in which the book is written should leave nurses with a vivid and lasting memory of these lectures. The book is divided into 18 chapters, some of which are especially good, and cover the whole range of medical teaching in general, without attempting to be fully inclusive. Dr. Clark-Kennedy has not modified in any way his informal talks to the more formal style of the printed word.

Chemical Constitution and Biological Activity

W. A. Sexton, B.SC., PH.D., F.R.I.C. London: E. & F. N. Spon. 1949. Pp. 412. 55*s.*

This valuable monograph provides a detailed review (up to the middle of 1947) of the broad field of scientific investigation indicated in its title. Though intended primarily for chemists, it will be valued as a book of reference for pharmacologists and for all concerned in the study or teaching of applied biochemistry. A brief historical introduction gives the chief landmarks in the study of the mechanism of the action of drugs, indicating the contribution of many sciences. Systematic investigation of the biological activities of series of derivatives has made it possible to predict how a desired property may possibly be achieved by chemical modification, often starting from a natural substance which has been used empirically with success. More recently, biochemical studies have given indications of the types of substance likely to be effective as inhibitors of metabolic reactions. The first of the five chapters on general principles supplies a brief survey of structural biochemistry. Others discuss the chemical mechanisms of drug action, the effects of physicochemical factors, and the changes undergone by drugs in living organisms. The account of the effects of specific chemical groupings on biological activity is especially notable. The remaining sixteen chapters deal with such things as the structure and functions or reactions of the components of the vitamin-B complex, of vitamin K, of choline and derivatives, and of porphyrins. The sulphonamides and antibiotics are briefly reviewed, and so are many dyes and other substances active against bacteria, fungi, protozoa, insects, and parasitic worms. Antigens [illegible] and substances related to [illegible] is appropriate that the section on antimalarial drugs should be extensive, for the author is a director of research in the laboratories of the firm responsible for the synthesis of proguanil ('Paludrine').

Intestinal Intubation

Meyer O. Cantor, M.S., M.D., F.A.C.S., *assistant attending surgeon, Grace Hospital, Detroit.* Springfield, Ill: C. C. Thomas. Oxford: Blackwell Scientific Publications. 1949. Pp. 333. 55*s.*

Just over forty years ago Einhorn and Gross first demonstrated the method of obtaining duodenal secretion by means of a small metal olive attached to a long thin rubber tube which could be swallowed and allowed by its own weight to pass beyond the pylorus. Twenty years later Wangensteen began to apply this method to the treatment of certain cases of intestinal obstruction; and since then many varieties of tube have been introduced —notably the double-lumen tube, tipped with an air-filled balloon, now called the Miller-Abbott tube. Dr. Cantor is well known for his work on intestinal intubation, and all gastro-enterologists will welcome this authoritative and exhaustive book. Beginning with the history of his subject, and offering detailed instructions for the practical use of the various types of intestinal tube, Dr. Cantor covers every aspect of this important method of treatment and investigation. Much that he says will interest general physicians and surgeons, and many of his points are certainly not fully appreciated by all those who advocate intestinal decompression for every form of abdominal distension. The sound physiological and scientific background is satisfying, and even if he is perhaps too enthusiastic at times about the merits of intestinal intubation all will agree that he has done a fine piece of work in collecting and summarising present knowledge on this subject.

The Psycho-analytic Study of the Child

III/IV. Managing Editors: Anna Freud; Heinz Hartmann, M.D.; Ernst Kris, PH.D. London: Imago Publishing Company. 1949. Pp. 493. 35*s.*

"Clear and distinct ideas" have perhaps never had any great appeal to the Anglo-Saxon mind; the extent to which the works of Freud have been accepted is proof, if proof is needed, of how well we can get on without sharp definition. Nevertheless, some of the Latin virtues might have saved some misconceptions and some schisms and heresies, even in this field. Now that the time has come for restatement of Freudian developments, might it not be more precise statement? This is just what we do not get in the papers, by various authors, collected in this volume. Instead there is this kind of thing: "If certain regularities do occur in the course of this procedure we will consider them in the nature of approximations, an orientation, as it were, within the map of the ontogenesis of sexuality." And this is no isolated example. There are only three papers offering any quantitative statements: those by Dorothy Burlingham, on twins, J. Louise Despert, on the dreams of preschool children, and Rene A. Spitz, on autoeroticism in the first year of life; and of these only the last could be called statistical. Mill's methods are applied, and the conclusion, reached in terms of concomitant variation, is that the better the relationship between the mother and child, the more likely the child is to show autoerotic behaviour. If true, this is interesting; but it is a pity that this group "showing excellent mother-child relationships" contains only 17 members. Two of the best papers in the book come from the West Sussex Clinic. The late Dr. Kate Friedlander distinguishes between antisocial and neurotic children. Antisocial children come from homes generally recognised as bad, whereas the boarding-out officer or welfare worker may pass as good the home where appearances are kept up to conceal a reality of "sado-masochistic" horror, richly productive of neurosis. Miss Lydia Jacobs writes intelligently on the problem of advising mothers in a child-guidance clinic. Many of the other papers contain very interesting material, but the uncertainty about what it all means is, in the end, too much of a deterrent.

THE LANCET

LONDON: SATURDAY, MAY 13, 1950

Hardship

Of the doctors whose fortunes were changed by the coming of the National Health Service, one group was particularly hard hit financially. These were the general practitioners with numerically small practices. They were working either in the countryside or in towns where, before the appointed day, private practice had been relatively remunerative. The number of patients they looked after was below the average number in a doctor's care throughout the country; but their load of work was not proportionately less, because more attention was expected of them by their patients.

The Act gave all principals established in general practice the right to continue in practice in their own area—a wise decision not only because it was obviously undesirable to uproot a proportion of the established doctors, but also because a man who has served for some years in a community is a greater asset to that community than he could for some time be to any other. Most practitioners exercised their right to stay in their own practice area, and many then found that the almost universal acceptance of the national service by their patients reduced their income without reducing the load of work. This situation had been foreseen in so far as sparsely populated and truly rural areas were concerned, and early adjustment of the mileage and inducement funds did much to ease initial hardships here. But these measures offered the urban practitioner with the small practice no relief at all, and it became harder and harder for such practitioners to meet their fixed commitments. A few of the younger ones gave up practice in the well-doctored areas where they had been practising and sought places as partners or assistants to doctors in underdoctored areas, many of whom now found their practices exceeding the statutory size. It was not so easy, however, for older men to do this. Their personal and family ties were stronger in the towns they had so long served, and even when they were willing to move it proved hard to find alternative places in which to practise. The busy doctor looking for help with an impossibly large practice prefers a young and energetic assistant to someone his own age or older —particularly someone who has grown up in the less hurried atmosphere of a small practice. Even executive councils have shown themselves unwilling to award a vacant practice to an older man if a capable younger man is available, as he almost always is. So most of the doctors with small practices stayed on, trusting that relief might come when the negotiations for the increase in the practitioners' pool were completed. As their hopes of help from this quarter fell, and the continued hardship they were experiencing became more apparent to all, it was decided last year that claims might be made against the moneys remaining in the Inducement Fund to alleviate this hardship. If the doctors would send in a statement of their incomes and expenses before and after the appointed day, and would make a claim for help, their position would be considered, and where appropriate a grant would be made. But this was all rather vague, and it savoured too much of charity. Nobody had any clear picture of what constituted hardship, and few practitioners seemed willing to appeal for this type of help. Moreover, those that did appeal often found obstacles in their way. Some were told that the area in which they were practising was not an "inducement area" and so they did not qualify for grant. Others who had experienced heavy falls in income were regarded as not suffering hardship, because their net income still exceeded an empirically fixed basic minimum. Even when a claim was agreed, it was not very clear how the sums granted were assessed, except that they were expected to be sufficient to bring the doctor's income back to this same universally applied invariable minimum. Altogether the scheme was felt to be neither equitable nor sufficient, and it was little used.

The Ministry of Health, after consultation with the General Medical Services Committee, has now placed these hardship grants on a very different and much more satisfactory basis. But, though a circular letter has gone out from executive councils notifying all practitioners of the new conditions of grant, it does not seem that the advantages of the altered scheme are yet well appreciated by many of those whom it is meant to help. The important changes that have been made are that claims will now be entertained from all areas, and not only from areas which would normally attract an inducement payment; that hardship will be measured not on net income remaining but on the difference in net income before and after the appointed day; and that the amount of relief given will bear a definite relation to this fall in net income.

> "The intention," to quote from the circular letter, "is to assist a practitioner who has suffered a severe loss of income as a result of the introduction of the Service, by making good some part of the loss and so helping to tide over a difficult transitional period. The circumstances of all such cases will be reviewed annually, and, though it is recognised that payments may have to be made in certain cases over a number of years while the doctors adjust themselves to the new circumstances, it is contemplated that such payments will be on a descending scale."

This quotation shows clearly the purpose of the grants. They are meant to give immediate assistance to the general practitioners who have been hit most hard. The claims are to be dealt with in the greatest possible confidence by a small subcommittee of the executive council and the local medical committee, and retrospective payments back to the appointed day are contemplated.

It is to be hoped that as many doctors as are entitled to benefit from this award will apply to their executive councils for the appropriate claim forms, and will make their claims without delay. But these grants, however welcome as short-term relief, are in no way a permanent solution of the problem of enabling the doctor giving diligent service to a smaller-than-average list to earn an adequate income. For one thing they are on a diminishing scale and so give no lasting help; for another they apply only to established doctors who can prove loss of net income, and will therefore be of no avail to the newcomer to practice. The eventual answer will probably be found to lie in a graded capitation fee, allowing proportionately more for the first 1000 (or other agreed figure) on a principal's list of patients. This seemed to be within reach, and would have been introduced if money had been available to augment the practitioners' pool. But even without such augmentation the Conference of Local Medical Committees must soon consider whether in equity it should not still propose modification of the distribution scheme so as to alleviate the lot of the doctors in areas where lists are small and static. The new grants should be a very present help, but they will not in themselves banish that sense of hopelessness and frustration felt by so many who find themselves working quite as hard as before, and usually harder, to earn an income which persistently remains below their needs. Such men and women can fairly expect that ways will be found to pay them properly for their work. If this were done, hardship grants would not be needed, for real hardship would no longer exist.

Aureomycin and Growth

THE borderland between bacteriology and nutrition is attracting many investigators these days, and their findings seem likely to have valuable practical applications in stock-breeding as well as in medicine. Last year STOKSTAD and his co-workers[1] in New York reported that the addition to the diet of a factor obtained from cultures of *Streptomyces aureofaciens*, the organism which produces 'Aureomycin,' would enhance the growth of chicks receiving a feed with soybean meal as the source of protein and an adequate amount of vitamin B_{12}. The same effect was observed by others in young pigs[2] and young turkeys.[3] Now, at the national meeting of the American Chemical Society in Philadelphia, STOKSTAD and JUKES have reported some important further work on this subject.

The growth-promoting effect was observed with whole cultures of the aureomycin-producing mould, with fractions that contained and others that did *not contain aureomycin*, and, though less regularly, with crystalline aureomycin in very small quantities —12 mg. of aureomycin in 1 lb. of food produced a well-marked response. The effect was quite distinct from that attributable to vitamin B_{12}, which cultures of the mould contain. This was clearly established by including adequate amounts of vitamin B_{12} in the experimental diets, and also by showing that aureomycin enhanced the growth of animals fed on diets with fish meal as the source of protein and therefore rich in "animal-protein factor," with which vitamin B_{12} seems to be identical. In seeking to explain how aureomycin increased the growth of young chickens, pigs, and turkeys, STOKSTAD and JUKES observed that the growth response was greatest when aureomycin was added to diets providing suboptimal amounts of vitamin B_{12}. This led them to think that aureomycin somehow reduced the animals' requirement for vitamin B_{12}. Following up the observation of MOORE et al.,[4] that succinylsulphathiazole hastened the growth of animals given a synthetic diet, STOKSTAD and JUKES confirmed that succinylsulphathiazole also increased the growth of chicks given one of their experimental diets, though the response was less than with aureomycin. By analogy, therefore, STOKSTAD and JUKES argue that aureomycin may act not by supplying an unknown nutrient but by altering the intestinal microflora so that a smaller amount of vitamin B_{12} has to be supplied in the food.

The economic importance of this work is clear, for in 3–4 weeks young, rapidly growing animals receiving a small quantity of aureomycin were in most experiments 25–50% heavier than those not given aureomycin. The scientific implications are also important. Nutrition is a meeting-ground of many scientific disciplines, and this work is a challenge to the inadequacy of our understanding of the rôle of the intestinal microflora in nutrition. Here the problem is to devise adequate methods of characterising the bacterial population of the intestinal tract, and so identifying the changes that result from alterations in the diet. In this difficult task, as MASSON[5] and NASR[6] demonstrated to the Nutrition Society at Aberdeen, there is much to be learnt from the proper use of modern microscopical and histochemical methods. BAKER[7] has long insisted that the application of such methods, and an intelligent interpretation of their results, is the most helpful starting-point and an essential control for the cultural and biochemical studies necessary to complete our knowledge of the nutritional consequences of changes in the intestinal microflora. At present these consequences seem more often to be vaguely postulated than demonstrated.

Protomedicus Anglorum

IF the preposterous Austrian title of *protomedicus* were revived for England and Wales, the man with the best claim to it would be, of course, a Scot Sir WILSON JAMESON, chief medical officer to the Ministries of Health and Education, retired on May 11 after ten years' service covering the most profound changes in medical organisation that this country has seen. Happily, when he took office in November, 1940, at the shortest notice, he had qualifications not even exceeded by those of his first and most distinguished forerunner, Sir JOHN SIMON. Well grounded in the practice of local public health through service in four London boroughs, in his period as dean of the London School of Hygiene and Tropical Medicine and professor of public health in London University he had been brought into personal touch with both the academic and administrative sides of medicine to an extent hitherto unknown. Add to that a wide experience as medical adviser to the Colonial Office (an experience by no means limited to a desk in Whitehall); the co-authorship of the standard textbook on public health; a gift for establishing har-

monious relationships; and a real sympathy with those, however junior, worried by personal and other problems, and it is clear that he combined at least many of the ingredients needed for success.

In the dark days of 1940 and 1941, the new chief medical officer might well have thought it enough to cope with the urgent and immense problems that arose day by day. But from the beginning JAMESON strove to make permanent improvements in machinery and relationships and to use each crisis for an advance. Out of the food situation came a permanent policy for protecting the nutrition of the "exposed" classes; and the success of this policy was recognised by the Lasker award given by the American Public Health Association to the British Ministries of Health and Food in 1947. Similarly, war-time epidemiological and other health problems were used to establish close and happy relations with the other Allies, notably with the U.S.A.; and Sir WILSON's famous broadcast on venereal diseases in October, 1942, did much to break down barriers which till then had prevented these diseases being treated on their epidemiological merits. He withstood the official and other fears expressed before this broadcast, and the result was his complete justification, the public reaction being for more and franker information. Other noteworthy changes included the establishment of a nursing division in the Ministry of Health; the entry of the Ministry into the field of health education of the public, notably in the "coughs and sneezes" and the anti-V.D. campaigns; and the integration of the medical branches in other departments by means of informal weekly conferences with their chiefs. As a member of the Goodenough Committee and otherwise, he showed his continued interest in medical education, and his frequent pleas for interchange of doctors between the British and the Colonial medical services, and for free movement of young doctors around the Commonwealth, were a reminder that medicine does not begin and end at home.

His Harveian oration of 1942[1] expressed his philosophy of war as an opportunity as much as a disaster for public health, and in it he showed how international coöperation might be aided by preventive medicine, as had happened before. Even at that early stage he predicted the changes that might follow:

> "Most of us who served in the period 1914–18 can recall how we looked forward to the time when we should return to the kind of life we had been leading before enlistment, to the practices or the appointments we had left, eager to get back to things as we knew them before the war clouds burst. Not so in this war. There is everywhere a conviction that great changes lie ahead of us and a desire so to plan the measures designed to meet the national emergency that some permanent good may be derived from them when the world is once again at peace."

Great changes did indeed come; and the end of the war brought not comparative relaxation but even heavier—and more complex—work and responsibilities. During the troubled period of the inception of the National Health Service JAMESON's gift for what may be called "organising understanding" stood the country and the profession in good stead. He had to explain the doctors' point of view to Ministers and administrators and in turn to present to the doctors the sometimes unpalatable proposals of the politicians. He had at once a strong belief in the ultimate benefits of an organised service and a deep loyalty to the profession, and he worked incessantly to reconcile the two. As the chief representative of medicine in the Ministry, he did all he personally could to ensure that, in HARVEY's words, doctors should "for the honour of the profession continue in mutual love and esteem among themselves." The split which he so much dreaded was avoided, and if the service today has grave defects, especially in the balance between its branches, he has never been one of those who expected immediate success in so great and complex an undertaking. In particular, his policy of broadening the Ministry of Health by the introduction of part-time specialist advisers of high calibre, and his insistence that the rewards of clinical skill should not be subordinate to those of the administrator, have gone far to build a sound basis for the future, and it is ill luck that national policy should have created a temporary crisis in his own department at the time of his departure.

The many people who like to call themselves his friends will be glad that JAMESON is relieved of his ten years' strain of office; but it would be a great pity if the experience and good sense he possesses were not retained in the counsels of the nation. It is easy to think of at least one other place where he could continue, in part, the kind of public service in which he has excelled.

Annotations

THE KING AT MILL HILL

NOWADAYS there are none too many big new buildings to be opened, and the inauguration of the National Institute of Medical Research at Mill Hill on May 5 was a national event, receiving full recognition as such. Before a distinguished assembly in the Fletcher memorial hall, Viscount Addison, F.R.C.S., as chairman of the Medical Research Council, gave the King and Queen a brief account of the project and asked His Majesty to perform the inauguration. In so doing, the King said that the institute exemplifies "that spirit which inspires the State and science to work together for the health and happiness of mankind. The results of this union are available to all without distinction of race, colour, or creed; and many families here at home, and indeed throughout the world, have reason to be grateful for the benefits which have been brought about by medical research." After the ceremony, Sir Charles Harington, F.R.S., director of the institute, presented to their Majesties members of the staff of the Medical Research Council, with the heads of divisions and others chiefly responsible for the researches of the institute. Later the King and Queen saw some of the departments. The building, which was described in our last issue, will ultimately accommodate about 100 qualified scientific workers and 250–300 ancillary staff, and it surprised some of the visitors by its size; its working conditions will be the envy of most investigators elsewhere in this country. The opening, very properly, was as notable an occasion as it could be made; for the institute's past record suggests that its staff will make the most of the new opportunities they are offered. As one guest said on leaving, "This place is for use, not show. Great things are going to be done here."

THE CHANGING FACE OF NURSING

IN a realistic survey[1] of the nurse's social and economic position, the Nursing Reconstruction Committee of the College of Nursing have avoided concrete recommendations and contented themselves with summarising matters of broad principle. This committee was set up in 1941, with Lord Horder as chairman, and has already published sections of the report dealing with the assistant nurse, education and training, and recruitment. In the new section, demand and supply are properly considered in relation to the population and the labour market. The committee note that by the end of 1951, in Great Britain, the number of women between 15 and 39 (the ages at which most women seek employment) will probably be at least 230,000 lower than at the end of 1946; and that this shrinking pool will have not only to carry the current load of work done by women but will have to replace the young people withdrawn from the labour market by the raising of the school-leaving age, supply more teachers to the schools and county colleges, and replace youths called up for National Service. Moreover in 1939 there were over 6 million women gainfully occupied, of whom perhaps 500.000 were doing work demanding standards of intelligence and education not lower than those required in nursing. Since the Nursing service alone now demands some 200,000 people, the committee press home the important lesson that the time has come to economise our experts in nursing to the utmost. We can no longer afford to use qualified women in posts which make no demands on their skill, or even to admit large numbers of students who will never complete their training. It seems clear to them that we must find out how much of the work at present assigned to nurses, trained and in training, can be done by other people. In hospitals, for instance, domestic and clerical duties come under this heading; in welfare clinics, babies can be weighed and food supplements handed out by someone other than a State-registered nurse. They conclude that a large body of subsidiary workers is essential, though they hesitate to assert that these should be either assistant nurses or orderlies. Which are employed, they say, can only be decided by experiment, and will often depend on the kind of workers available in a given neighbourhood. They hope that the revised and shortened training for assistant nurses will help us to develop a large stable element in our nursing service; and they speak warmly of part-time nurses, who in just over three years have increased from 3000 to 26,000. Part-time nursing, begun as a temporary expedient for the care of the chronic sick, bids fair to become a permanent contribution to the health service; but it will only do so, they imply, if part-time nursing schemes are adequately prepared and administered with sympathy and understanding. The rates paid to part-time nurses are based on the salary and emoluments of comparable grades of full-time nurses; and the committee note that undervaluation of the hospital nurse's emoluments has brought the hourly rate of pay of even fully qualified part-time nurses below that of a home help—an anomaly which they say is in course of correction.

Since nursing is a profession, the committee believe that hours of work should be subject to negotiation but not legislation. Where overtime is necessary, it should not be compensated by extra pay, but by a return in time off duty later; and they make the important point that when a hospital finds itself unable to "pay back" overtime to its nurses, then it is offering service beyond its powers. This point has never been given sufficient weight in the past, and the custom of laying every new load on the nursing staff has been one of the causes of wastage from the profession. They believe that the financial prospects in each field of nursing should be such as to retain those who would choose it on professional grounds. The ward sister, for example, should not have to give up her chosen field of work if she seeks advancement. Additional qualifications should be recognised financially; and nurses should if necessary receive a bonus as an inducement to work in unpopular fields. Nurses are placed at a considerable disadvantage, it seems, by the undervaluation of their emoluments already mentioned; among other things it means that they get a smaller pension on retirement than would otherwise be the case, and that the nurse who tries to live out is not able to meet her running expenses out of the sum allowed in lieu of emoluments. Today, the committee consider, the hospital must revise its views on the need for stable resident staff: indeed, they even go so far as to say that nursing may soon be regarded as a non-resident profession like any other: and for this reason the basic salary should always be the gross salary. A more realistic evaluation of emoluments they say, together with the introduction of the straight-shift system of working hours, would enable many more nurses to live out if they wished—advances which we have long advocated. They even think that there may be a growing tendency for student nurses to live at home, though they note the demand of home distractions on time and energy. The committee believe, too, in the principle of equal pay for equal work from men or women, coupled with dependants' allowances. In discussing the nurse's health they say that whether or not communicable diseases, especially those causing long incapacity, should be "scheduled diseases" must depend on the facts. In the case of tuberculosis for instance, if it can be proved to be an occupational hazard then the nurse should be adequately covered against the risk.

The report goes far beyond anything so far published about the state of the nursing service; and the committee, in their readiness both to face contemporary facts and to look for ways of turning them to good account, make a refreshing and practical approach to a well-worn problem.

RHINELAND EPIDEMIC OF ENCEPHALITIS

THE great advances in our knowledge of the many kinds of non-suppurative encephalitis in the 34 years since Economo described encephalitis lethargica have mainly resulted from virus research and the correlation of neurohistological and experimental findings with clinical features.[1] Epidemiological investigations have contributed to the understanding of some forms, such as Russian spring-summer encephalitis and St. Louis encephalitis, but until the last few years there has been no opportunity for such investigations in Europe since the world-wide epidemic at the end of the first world war, apart from the study of postvaccinal encephalomyelitis in Holland.

Lately, Bader and Hengel[2] have reported on a small epidemic which occurred in the Rhine area in 1947. Its time-relationship to the second world war and the fact that it coincided with a large epidemic of influenza at first suggested that it was identical with encephalitis lethargica. But the Rhineland disease was more benign and apparently did not leave parkinsonism as a sequel. There were also some significant differences in epidemiology between the two. Lethargic encephalitis spread rapidly and widely, and its incidence was highest in the colder months; it attacked people of all ages, in town or country, and contact infection, though rare, was established on several occasions.[3] The 1947 epidemic was almost entirely restricted to a small area on the left

bank of the Rhine. The infection showed a preference for rural areas and the peripheries of towns. Sporadic cases were the rule; among the 53 cases studied there were only 2 instances of more than one patient being in the same street or the same building, and there were no examples of multiple cases in a family. The incidence was highest in the hot months, and none of the patients were under 7 years old. Case-to-case spread was excluded and contact infection from domestic animals seemed highly unlikely. The conclusion drawn from the epidemiological observations was that the reservoir of the virus was among the wild field animals and the disease was transmitted by insect vectors. This view was supported by the observation of a tick engorged with blood on the arm of one fatal case, but the tick appeared to play only a minor part in the spread of the disease, the main vectors being thought to be mosquitoes, such as *Aedes vexans, Culex*, and *Theobaldia*. The epidemic had many features in common with forms of "summer encephalitis" such as louping-ill, Siberian and Japanese B encephalitis, and especially St. Louis encephalitis. Some of the viruses of these varieties of summer encephalitis are immunologically related though not identical. Thus, the serum of mice immunised against the virus of Japanese B encephalitis has some protective action against the St. Louis virus.[4] In the Rhineland epidemic all attempts at animal transmission were unsuccessful, and the neutralisation of herpes virus by the sera of 3 of the patients is, as Bader and Hengel point out, of no significance.

EUTHANASIA

THE Dean of St. Paul's having told the Voluntary Euthanasia Legalisation Society that its proposals accord with the Christian conception of human right and duty, the Archbishop of Canterbury has expressed his personal disagreement. Public opinion, it is clear, has not yet reached that certainty which is indispensable to the success of the campaign to change the law.

Apart from the religious and the civic aspects of the matter, it presents a special problem to the medical profession. This is illustrated by the recent trial of Dr. Hermann Sander in New Hampshire. He was charged with murder, in that he had made four injections of air into the veins of a patient suffering from incurable cancer. After a three weeks' hearing he was acquitted. This, however, was not the end of the case. The New Hampshire State Board of Registration in Medicine revoked his licence to practise, though he is allowed to apply for reinstatement in two months' time. The board's decision, given in some detail by the *New York Times* of April 20, may be summarised as follows. The records of the hospital concerned indicated that Dr. Sander injected air into the patient's body last December; at a hearing by the board last month he admitted the fact, though he did not positively state whether or no he actually penetrated the vein. He told the board that he thought the patient was dead when he made the injection; his counsel described this as a senseless act for which no adequate explanation was possible. Dr. Sander contended that he had done no wrong because he was sure that he had not killed his patient. The board state that they are not concerned with the question whether the patient was alive or dead; it is common medical knowledge, they say, that such an injection of air into the body can serve no useful purpose and that every precaution is taken to avoid introducing air into a human vein; a physician's moral obligation to his patients and his profession is to engage only in medical practices which are designed to cure or alleviate; "any act of a physician which is not so designed fails to meet the moral standard of the medical profession": no physician can be allowed to perform a senseless act for which no adequate explanation is possible. Thus the board find that Dr. Sander's "moral character," within the meaning of the section in the relevant statute, is such as to require the revocation of his licence to practise.

Euthanasia, it was once observed in the *Spectator*, is no more demoralising than capital punishment. Its ethical problem is akin to that of suicide which so long divided the ancient philosophers. Lecky in his *History of European Morals* collects their contradictory opinions. To Pythagoras and Aristotle, for instance, self-destruction was an antisocial act comparable with a soldier's desertion from his post. Virgil in the *Aeneid* depicted the awful fate of suicides. Seneca and others, on the other hand, saw no harm in the deliberate escape from intolerable conditions. In this country we call it manslaughter if a person, having the care of a child, causes or hastens its death by failing to provide proper medical aid, or if he or she, having undertaken to look after anyone who is helpless through old age, unsound mind, or other infirmity, causes death by culpable neglect. Euthanasia is not yet classified among the justifiable homicides.

CHILL AND THE LIVER

LATTERLY the emphasis laid on nutrition in the animal economy has diverted attention from physical environmental factors such as cold, damp, and draughts. Hence it is good to hear of some observations by Howie and his colleagues[1 2] at the Rowett Research Institute. From birth till weaning at eight weeks, three different groups of pigs were kept (A) in open pens in cold, draughty, and often damp byres with non-insulated floors, (B) in warm wooden ark shelters or electric hoovers, and (C) under the same warm conditions as the group B, with the addition of an outdoor concrete run. By fifteen weeks after birth there had been 16 deaths among the 30 pigs in group A, and 5 among the 21 in group B, but none among the 16 in group C. The principal necropsy findings were ascites (150 to 700 ml.) and severe "nutmeg" change of the liver. Microscopically the liver showed severe sinusoidal congestion, some fatty change, centrilobular necrosis, and some fibrosis—the last being most advanced in the animals surviving longest. Naftalin and Howie[2] call attention to the similarity of their findings to those of McGowan[3]; but, unlike McGowan, they were unable to prevent the lesions by a supplement of iron, and they conclude that physical factors in the environment are primarily responsible. Despite the striking loss of appetite observed in the animals of group A from about the seventeenth day onwards, the lesions are quite distinct from those observed in experimental nutritional deficiency.[4] On the other hand, very similar lesions are found in the liver in severe passive congestion; and, since the other organs were in general unaffected in their pigs, Naftalin and Howie suggest that vascular disturbance within the liver was a major cause. The frequency of ascites, without œdema or effusion elsewhere, supports this hypothesis. It is true that, wherever liver necrosis is found, the action of a toxic agent must be considered; but Wallach and Popper,[5] have drawn attention to several histological minutiæ which help to distinguish toxic lesions from those of passive congestion, and both the illustrations and description of the lesions in the pigs conform to the "congestive" or ischæmic type. The evidence so far obtained thus tends to incriminate the richly muscular hepatic vascular tree, which may be presumed to go into spasm when the bare abdomen is applied to cold damp concrete. Anæmia (present in most of the affected animals), and the increase in metabolic rate associated with exposure to cold, could

be expected to enhance the effects of any centrilobular ischæmia produced by venous spasm.

As Best[6] has shown, in rats, that alcohol is no more toxic to the liver than an isocaloric quantity of sucrose, perhaps the indubitably higher incidence of cirrhosis amongst alcoholics in this country arises not from the action of the alcohol on the liver but from the predisposition it engenders to lie, like Howie's pigs, with the abdomen close pressed to cold damp concrete.

CHILDREN AND THE CINEMA

CERTAIN subjects inevitably rouse strong expressions of opinion; and the slighter the evidence the stronger, very often, are the opinions. The effect of the cinema on children falls into this class; and the departmental committee who have just reported[7] are to be congratulated not only on presenting some facts and figures but on dealing temperately and analytically with such expressions of opinion as have come their way.

They established that the proportion of children going to the cinema is very high. Children between the ages of five and fifteen in England, Wales, and Scotland number just over 7 million, and more than 6 million of them (88%) go to the cinema from time to time. Of the large numbers questioned on behalf of the committee, 31% go to the cinema regularly once a week, and another 21% twice a week or oftener. (In the committee's view children who go regularly more than once a week are going too often.) Since 1931 the percentage in each of these categories has risen, and the percentage of those who do not go at all has fallen from 12 to 6. About a dozen licensing authorities regulate the admission of children to cinemas on Sundays, and some attempts have been made to exclude children from late performances. The committee advise that no unaccompanied child under twelve years of age should be admitted to, or allowed to remain in, a cinema after 8 P.M.

The classification of films as "U" (for universal exhibition), "A" (for exhibition to adult audiences), and "H" (horrific, for exhibition when no children under sixteen are present) has not been effective in protecting children from witnessing unsuitable films. The committee recommend that the following should be substituted for it:

1. "X" films, to include the present "H" category, from which children should be absolutely excluded.
2. "C" films, to be shown at children's cinema exhibitions.
3. Advisory category "U," which would be family entertainment, and advisory category "A" which would be preferably for adults. Admission of children to the showing of films in these categories would be unrestricted.

On the whole, though they found much to criticise, the committee commended the efforts some cinemas and organisations are making to cater suitably for children at Saturday matinées, and at Saturday-morning cinema clubs. The programmes are difficult to compose, because films made specially for children are so scarce. A great step forward was taken, however, when, in 1944, Mr. J. Arthur Rank decided to produce entertainment films for children, and sought the help of Lady Allen of Hurtwood in forming the Advisory Council on Children's Entertainment Films.

There seems to be little evidence either way about the physical effects of going to the cinema: whether the cinema is good or bad for the eyes, or whether fatigue in children can often be attributed to visits to the pictures, has yet to be settled. Some children are frightened or over-excited by films; and the committee urge cinema managements to cut out from children's performances serials based on suspense or violence. Much more harmful are films which, paying lip-service to morality, yet "contain sequences that are brutal, antisocial or licentious." About these the committee have no doubts: "we think they are bad and we should like to see them banned altogether to children." More insidious damage, however, is done by "the regular portrayal of false values." Thus the children are repeatedly called upon to admire worldly success—riches, power, luxury, or public adulation—as the greatest good; and they are given no reason to suppose it matters much how these are attained. This, the committee think, may be more pervasive and dangerous than depiction of crime or impropriety. Mothers, questioned about the films their children saw, wanted more emphasis on kindness, both to people and animals, and on ordinary happy family life. They wanted their children to see more stories of nobility and heroism, more entertaining travel films and historical dramas, and more films of open-air country life.

A large number of inquiries were made to decide whether the cinema causes or fosters juvenile delinquency. Opinions in the replies were almost equally divided. Among 38,000 children dealt with in juvenile courts during the six months ending June 30, 1948, only 141 cases of delinquency and 112 cases of moral laxity appeared to have any direct connection with an incident in a film seen by a child. Again, 39,238 children between eight and fifteen years of age in England and Wales were found guilty of indictable offences in 1948; but some 3 million children of those ages were attending the cinema at the time. Taking the evidence as a whole, the committee concluded that it did not "fasten on the cinema any primary share of responsibility for delinquency or moral laxity of children under 16." Mrs. Robert Bower added a minority report, affirming her belief that the cinema, in its present state, is a factor in producing delinquency. But she, in accord with the rest of her colleagues, was satisfied that the cinema could equally be a great power for good.

CHANGES IN THE MEDICAL BILL

CONTROVERSY can be very stimulating but consultation is often very effective, and the amendments to the Medical Bill proposed by the House of Lords (see p. 921) should increase its value. Though health centres are still surgeries in Spain, it is sensible that the idea that general practice is a suitable training-ground for the medical apprentice should be recognised. Lord Webb-Johnson's amendment that the length of the apprenticeship should be deleted from the Bill is not introduced with any thought of shortening the period but only to ease what may well be a difficult beginning and thus perhaps make possible an earlier start.

Most of the other important amendments deal with the constitution of the General Medical Council itself, and they meet some of the points raised by medical bodies.[1] The directly elected members are increased from nine to eleven, and Wales is given a representative of her own. The increase of the lay representatives on the disciplinary committee from one to two received medical support from Lord Moran. This amendment was perhaps the more easily accepted as it is now suggested that the quorum of the committee should be reduced from nine to five, and that only exceptionally more than nine members should attend. There was a feeling that at least one of these should be a lay representative. This procedure is in line with that adopted in the recent Justices of the Peace Act. Lord Simon lent legal support to the view that a smaller committee has a keener sense of personal responsiblity, and the Lord Chief Justice went so far as to quote Coke's dictum: "you cannot get justice from a mob of judges."

Lord Webb-Johnson's amendment that the penalty for pretending to be a doctor should be raised from £20 to £500 was also accepted.

Reconstruction

THE FUTURE OF GENERAL PRACTICE *

R. J. F. H. PINSENT
M.A., M.D. Camb.

THE general practitioner is not normally a vocal person, and formerly his problems seldom found expression in the medical journals; but over the past five years there has been first a trickle, then a current, and lately a spate of articles, letters, and editorials drawing attention to the gross shortcomings which can exist in general practice nowadays. Many of these deficiencies existed before the passing of the National Health Service Act; the effect of this Act on the difficulties has been to alleviate a few, increase many, and create some fresh ones. It is now recognised that the practitioner lacks two things—time, and facilities for the proper conduct of his work. The concept of the health centre arose from the desire to remedy this lack.

ANALYSIS OF A PRACTICE

Here is described the result of an investigation carried out in one general practice (in a Midland industrial city) with the aim of ascertaining the particular difficulties in it, and the action required to enable the practitioner to carry out work compatible with the standard of his hospital training. The analysis of the work in this practice, serving 3200 patients (1680 panel and 1520 private), was based on items of service rendered for one year from Sept. 1, 1947. The distribution of these items over the year and by groups is set out in tables I and II. Table I shows that during the year 10,803 items of service were rendered. This represents an average of 30 per day; but, allowing for weekends and some time off duty, the weekday level is far higher; patients may have to be seen at the rate of 12–15 per hour if an ever-filling waiting-room is to be emptied in time for visits to be made.

TABLE I—DISTRIBUTION OF ITEMS OF SERVICE BY CONSULTATIONS AND VISITS

—	Consultations	Visits	Consultations and visits

Av. for calendar day ..	21	8	29
Totals for year ..	7738	3065	10,803

The need to earn a livelihood forces the doctor to take a large number of patients. The larger his list, the more thinly will his skill be spread. The danger of this dilution will continue until remuneration is based on the quality, and not the quantity, of his professional responsibility. The primary need, therefore, is for limitation of lists to, say, 2000 patients, with remuneration appropriate to the practitioner's work and status.

Much of the practitioner's day is spent on non-professional work; and the greatest cause of misused time is certification. Table III shows the experience in the practice under review. In the Welfare State the doctor has almost ceased to be a medical adviser, and instead has become a Mother Hubbard whom you "get something from," whether it be a certificate for sick benefit or extra rations, or a prescription for twenty aspirin tablets: consultations degenerate into requests for "my note" or a signature to a document. To justify himself the patient will enlarge on any symptoms he may have, causing the doctor to make some—probably negative—examination, thus taking further time. Yet the cause of that patient's attendance is simply the need for an administrative certificate "and another for my works, too, Doctor." The remedy lies in convincing administrators that the doctor should not be used as a filter between the patient's demands and available supplies, whether these be for insurance benefit or extra petrol. At the same time the public must be weaned of their belief that a doctor's "line" will procure almost anything.

SAVING TIME

The need for time-saving in clerical work is now acknowledged. Perhaps the one good thing to come out of the National Health Service, so far as general practice is concerned, is the universal medical-record envelope which, if the record is properly kept, could ultimately provide the statistician with invaluable material. But for the practitioner the increased number of cards means more filing, more replacing of cards, and more correlation of specialist reports—all of which takes professional time that could be better spent. However highly the ability to talk and write simultaneously may be developed, the records kept in a busy practice without clerical assistance cannot be accurate enough for serious statistical investigation, or even for helping the doctor to handle his own patients.

TABLE II—DISTRIBUTION OF ITEMS OF SERVICE BY GROUPS

Group of patients	Items of service per head	
	Consultations	Visits
Panel	3·5	0·6
Private	1·2	1·3

A further cause of wasted surgery time is that lost while patients undress and dress. Sometimes examination has to be omitted or to be carried out with inadequate exposure of the part concerned, simply because of the time that would be taken while layer after layer of clothing was painstakingly removed and replaced. Here the answer lies in an examination-room adjacent to the consulting-room. This is seldom found in the improvised domestic premises now in common use.

Much time that might be better used by the doctor is spent in dealing with trivial complaints requiring no more than the adult equivalent of "Mummy, kiss it better." Behind many of these complaints there may well be more. By their manner of presentation these cases, though serious, appear trivial; time may not permit of fuller investigation; and the opportunity for early diagnosis may be missed. Many more of these cases arise, however, simply from lack of education in health matters. These patients should be taught a sense of balance and proportion in health questions, so that they are not sent home with a bottle of medicine and an unsolved problem. This task of education the doctor cannot carry out alone.

* The investigations described here have already been recorded in a thesis for the M.D. degree, University of Cambridge.

be expected to enhance the effects of any centrilobular ischæmia produced by venous spasm.

As Best [6] has shown, in rats, that alcohol is no more toxic to the liver than an isocaloric quantity of sucrose, perhaps the indubitably higher incidence of cirrhosis amongst alcoholics in this country arises not from the action of the alcohol on the liver but from the predisposition it engenders to lie, like Howie's pigs, with the abdomen close pressed to cold damp concrete.

CHILDREN AND THE CINEMA

Certain subjects inevitably rouse strong expressions of opinion; and the slighter the evidence the stronger, very often, are the opinions. The effect of the cinema on children falls into this class; and the departmental committee who have just reported [7] are to be congratulated not only on presenting some facts and figures but on dealing temperately and analytically with such expressions of opinion as have come their way.

They established that the proportion of children going to the cinema is very high. Children between the ages of five and fifteen in England, Wales, and Scotland number just over 7 million, and more than 6 million of them (88%) go to the cinema from time to time. Of the large numbers questioned on behalf of the committee, 31% go to the cinema regularly once a week, and another 21% twice a week or oftener. (In the committee's view children who go regularly more than once a week are going too often.) Since 1931 the percentage in each of these categories has risen, and the percentage of those who do not go at all has fallen from 12 to 6. About a dozen licensing authorities regulate the admission of children to cinemas on Sundays, and some attempts have been made to exclude children from late performances. The committee advise that no unaccompanied child under twelve years of age should be admitted to, or allowed to remain in, a cinema after 8 P.M.

The classification of films as "U" (for universal exhibition), "A" (for exhibition to adult audiences), and "H" (horrific, for exhibition when no children under sixteen are present) has not been effective in protecting children from witnessing unsuitable films. The committee recommend that the following should be substituted for it:

1. "X" films, to include the present "H" category, from which children should be absolutely excluded.
2. "C" films, to be shown at children's cinema exhibitions.
3. Advisory category "U," which would be family entertainment, and advisory category "A" which would be preferably for adults. Admission of children to the showing of films in these categories would be unrestricted.

On the whole, though they found much to criticise, the committee commended the efforts some cinemas and organisations are making to cater suitably for children at Saturday matinées, and at Saturday-morning cinema clubs. The programmes are difficult to compose, because films made specially for children are so scarce. A great step forward was taken, however, when, in 1944, Mr. J. Arthur Rank decided to produce entertainment films for children, and sought the help of Lady Allen of Hurtwood in forming the Advisory Council on Children's Entertainment Films.

There seems to be little evidence either way about the physical effects of going to the cinema: whether the cinema is good or bad for the eyes, or whether fatigue in children can often be attributed to visits to the pictures, has yet to be settled. Some children are frightened or over-excited by films; and the committee urge cinema managements to cut out from children's performances serials based on suspense or violence. Much more harmful are films which, paying lip-service to morality, yet "contain sequences that are brutal, antisocial or licentious." About these the committee have no doubts: "we think they are bad and we should like to see them banned altogether to children." More insidious damage, however, is done by "the regular portrayal of false values." Thus the children are repeatedly called upon to admire worldly success—riches, power, luxury, or public adulation—as the greatest good; and they are given no reason to suppose it matters much how these are attained. This, the committee think, may be more pervasive and dangerous than depiction of crime or impropriety. Mothers, questioned about the films their children saw, wanted more emphasis on kindness, both to people and animals, and on ordinary happy family life. They wanted their children to see more stories of nobility and heroism, more entertaining travel films and historical dramas, and more films of open-air country life.

A large number of inquiries were made to decide whether the cinema causes or fosters juvenile delinquency. Opinions in the replies were almost equally divided. Among 38,000 children dealt with in juvenile courts during the six months ending June 30, 1948, only 141 cases of delinquency and 112 cases of moral laxity appeared to have any direct connection with an incident in a film seen by a child. Again, 39,238 children between eight and fifteen years of age in England and Wales were found guilty of indictable offences in 1948; but some 3 million children of those ages were attending the cinema at the time. Taking the evidence as a whole, the committee concluded that it did not "fasten on the cinema any primary share of responsibility for delinquency or moral laxity of children under 16." Mrs. Robert Bower added a minority report, affirming her belief that the cinema, in its present state, is a factor in producing delinquency. But she, in accord with the rest of her colleagues, was satisfied that the cinema could equally be a great power for good.

CHANGES IN THE MEDICAL BILL

Controversy can be very stimulating but consultation is often very effective, and the amendments to the Medical Bill proposed by the House of Lords (see p. 921) should increase its value. Though health centres are still surgeries in Spain, it is sensible that the idea that general practice is a suitable training-ground for the medical apprentice should be recognised. Lord Webb-Johnson's amendment that the length of the apprenticeship should be deleted from the Bill is not introduced with any thought of shortening the period but only to ease what may well be a difficult beginning and thus perhaps make possible an earlier start.

Most of the other important amendments deal with the constitution of the General Medical Council itself, and they meet some of the points raised by medical bodies.[1] The directly elected members are increased from nine to eleven, and Wales is given a representative of her own. The increase of the lay representatives on the disciplinary committee from one to two received medical support from Lord Moran. This amendment was perhaps the more easily accepted as it is now suggested that the quorum of the committee should be reduced from nine to five, and that only exceptionally more than nine members should attend. There was a feeling that at least one of these should be a lay representative. This procedure is in line with that adopted in the recent Justices of the Peace Act. Lord Simon lent legal support to the view that a smaller committee has a keener sense of personal responsiblity, and the Lord Chief Justice went so far as to quote Coke's dictum: "you cannot get justice from a mob of judges."

Lord Webb-Johnson's amendment that the penalty for pretending to be a doctor should be raised from £20 to £500 was also accepted.

* The investigations described here have already been recorded in a thesis for the M.D. degree, University of Cambridge.

HELP FROM NURSES

The long-term solution must be to reinforce general practitioners with nurses, even if this means reducing the number of nurses in hospitals; if the practitioner were enabled to do his work properly, far fewer patients would need hospital nursing. Possibly in future there will be devolution of work not necessarily requiring a doctor's care to suitably trained nurses, working in close collaboration with doctors, as in industrial medicine. It would be an advantage if nurses engaged on this work could have some secretarial training; and they should also be empowered to sign many of the documents which are at present valid only when signed by the doctor himself.

The procedure might be as follows. All new patients would be seen by the doctor, along with those told to see him on that day; and the nurse would see and attend to patients who had been told to report to her for a dressing, an injection, or, in the case of protracted illness, a repeat certificate. The nurse would refer back to the doctor any patient of whose progress she was in doubt, and other patients at intervals decided by the doctor. He would also see all patients for their final certificate on discharge.

Similarly, the nurse, if provided with means of transport, could lighten the doctor's visiting-list. The doctor, having answered all first calls, would delegate certain visits to the nurse, perhaps to give penicillin or to check an evening temperature; and some elderly patients who might otherwise remain unvisited could be added to the nurse's list for more or less routine visits, the doctor being kept informed of any change in the patients' condition. Though highly desirable, it would be economically unsound for practitioners to have the full-time help of a nurse, unless their lists were large; and then the work done by a suitable nurse might obviate the need for a medically qualified assistant, who would be released for independent practice elsewhere.

The nurse who is to assist the practitioner—much in the way that the houseman aids the specialist—would need to be selected from among those who are experienced and able to accept responsibility. Experience of district nursing should be an essential preliminary, and the existing home-nursing service should be retained as a training medium for these " general-practitioner nurses," and also as an aid to doctors whose lists do not warrant the employment of a full-time worker.

After a stipulated period " on the district," the nurse would be apprenticed to an individual doctor or a health-centre team, and thereafter she would sit for an examination comparable to that for the diploma in industrial nursing; by passing this examination she would qualify as a " general nursing practitioner," with improved status. Such a qualification might empower the holder to sign statutory certificates in her own right. It might also lead to the acceptance in a court of law of her testimony as that of an expert witness, thereby raising her status further in the eyes of her colleagues.

Her value would be greatest in the home, where the need for education of the patient is greatest. In time, perhaps, patients would recognise her as the first person to consult on minor ailments.

AIDS TO DIAGNOSIS

Whether working single-handed or with a general nursing practitioner, the doctor cannot give of his best if he is denied the diagnostic and therapeutic facilities whose use he mastered as a student. During the year under review, 19% of all patients referred to hospital were sent to a casualty department; and the reason was lack of facilities and time. In the same way some patients were referred to consultants because only they could order the investigations needed to establish a diagnosis which otherwise could have been made in the surgery. The remedy here would seem to be adequate radiological and pathological equipment of the new health centres; for it is doubtful whether the existing laboratory services could meet the demands of the many frustrated practitioners who are now forced to send their patients to specialists even to obtain a blood-count. In advance of health centres, small subsidiary laboratory and X-ray units might be set up in thickly populated and under-doctored areas. The practitioner's experience in sharing such a diagnostic unit with his colleagues might stand him in good stead when later they met at the health centre itself.

In the long run it might be well to include in health centres a ward annexe where the general practitioner could have charge of a few beds of his own. In such an annexe, which would be lightly staffed, the general practitioner would undertake the preliminary investigation of his own patients, with the help of the centre's radiological and pathological departments. Visits from hospital consultants would afford miniature refresher courses and bridge the gap between specialist and practitioner.

At present the practitioner is unable to offer the best service of which he is capable. A little breeze is beginning to blow through the valley of dry bones that is general practice. Our aim should be to fan this into a tempest about the ears of the administrators in whose hands practitioners placed themselves on July 5, 1948.

Special Articles

HISTORY OF NURSING

(FROM A CORRESPONDENT)

GREAT advances have taken place in nursing in the last ninety years. The Nightingale impetus has enabled the profession to meet the demands of a rapidly expanding hospital system in Great Britain and in Northern Europe, and in a rather different form in America. Its influence has spread through the older Continental systems and to a large extent drawn them into its own pattern. This country is proud of its central position in this world-wide movement, and in her *General History of Nursing*, a second edition of which has recently been published,[1] Mrs. Seymer quite properly reflects this sense of achievement. As one turns the pages one feels the onward march—the first training schools, the first attempts at organisation on a national basis, and the culmination (in Great Britain) of State registration in 1919, itself the starting-point of a series of similar enactments all over the world in ever-widening circles. On and on; how hospital nursing has been adapted to the various branches of public-health work; how the nurses rose to further heights under the stress of war; how there are now even paratroop nurses—here all is set out with much interesting detail and pleasant illustrations.

Many, however, are conscious today, as they were not twenty or thirty years ago, that behind this sense of achievement there is ground for anxiety. The rise in numbers has not been accompanied, it is whispered, by a rise in the quality of the nurses or of nursing; there has even, despite all the forward movement, been a real shortcoming. Apart from the numerical difficulty, the ideal that seemed within our grasp in the '20s has not been realised in its fullness. There has been criticism from outside, and attempts by working parties and others to offer solutions, but the keys offered have rattled in the lock. What light can history throw on all this?

It is here that the standard histories, of which Mrs. Seymer's is the most notable example, fail us. The history of nursing has not yet passed out of the stage of the chronicle into that of critical history. "Today," said Maitland, "we study the day before yesterday, in order that yesterday may not paralyse tomorrow." For such guidance we turn to Mrs. Seymer largely in vain. Is it possible, we must ask, to get below the surface and analyse the mistakes which have been made in years gone by, and to relate the history of nursing intelligibly to the social history of our times? If we could get the history right, we might be within sight of finding real and not pseudo-solutions to our problems.

---

[1] A General History of Nursing. (2nd ed.). By L. R. SEYMER, M.A. Oxfd, S.R.N. London: Faber & Faber. Pp. 317. 21s.

THE STATE EXAMINATION

Here we cannot hope to do more than look for pointers: let us try to test the matter by one or two examples. It is a defect in most of the accounts to be found on the shelves of a hospital library that the case against State registration by State examination is glossed over. It is coming to be forgotten by the younger generation that there is a possible alternative course backed by no less an authority than Miss Nightingale herself. We have to remind ourselves that her opposition extended to the whole conception of examination—"you cannot select the good from the inferior by any test or system of examination." The much-vaunted "Register" would not, she thought, raise the profession of nursing; it would do an injury to the better nurses by putting them on a level with the inferior, and to the profession by stereotyping a minimum standard. We have to remind ourselves too that here and there today there are to be found good judges who hold the same view.

How is the matter handled in this most widely read and most authoritative of the histories of nursing? Mrs. Seymer is too honest to pass without notice the long opposition to State registration, and she duly notes that "on no other subject in all nursing history has such controversy raged or such acrimonious discussion taken place"; but she quickly makes up her mind and proceeds to set out the "basic principles which lie behind all State interference"; to wit, "that on the one side the graduate nurse has a right to have her professional status and interests legally safeguarded, and on the other that the public ought to be protected against the semi-trained or untrained woman." On these questionable foundations she builds up the case for State registration, and the reader is referred to other sources for the views of the antiregistrationists.

Now here surely was matter for the most serious critical discussion; how far, in the light of subsequent events, was Miss Nightingale right, and how far was she wrong? Is it not at least arguable that she was more right than wrong; that a very small dose of State control—i.e., the inspection and approval of training schools—would have proved the better plan and have avoided most of the troubles under which we now labour? Impossible, says the nursing world with almost one voice; but is this not possibly because it has been led to think so by a selective presentation of the historical background? The group of ideas which carried the day in 1919 owed much to assimilation from non-nursing sources and was closely bound up with the movement for political emancipation for women. They have usurped the place of the Nightingale tradition in our historic perspective. Let us at least be clear that State examinations and "student status" itself—as contrasted with apprenticeship—have no claim to be considered part of the Nightingale tradition.

CURRICULA

Let us try a different tack. Speaking generally the medical profession has for many a year been critical of the amount of book-learning required of a nurse. An American doctor, writing as long ago as 1912, speaks of the modern curriculum which "not one pupil in a hundred in the training schools" can possibly master. "The builders of these curricula feel within themselves that the training schools are not up to modern demands [i.e., those of 1912] and they are attempting to correct this fault by setting up courses of study that would fill the want, but their pupils cannot measure up to them." How modern this sounds! Now the *General History of Nursing* is silent about this persistent difference of opinion; it is not even mentioned that in Great Britain the proportion of failures in the State examinations has often been high and has been the cause of concern, and this at a time when the numerical shortage was itself also serious. Of entrants who survive the preliminary training schools about 30% fail annually in the preliminary State examination and some 20% fail in part II or in the final. The total of those eliminated from continuing in nursing by examinations thus amounts to 44%. They can become assistant nurses, but that is another matter. The deterrent effect of these failures on recruitment to the profession can be well imagined.

Of course there is much to be said for at least some theoretical instruction; but the fact of this long-standing difference of opinion is passed over by Mrs. Seymer. It would not be fair to criticise her on this account, for she is but reflecting a very general attitude. But we must ask what sort of a history is it that can close its eyes in this way when it chooses? Is it well that those who, in a decade or more hence, will be our legislators on the General Nursing Council should get their history from sources which leave such large questions as this undiscussed?

THE AMERICAN SYSTEM

Or let us look across the water and see what has been happening in America. It is one of the merits of the book that it sets out plainly the distinguishing features of four systems of nursing organisation: the Nightingale system, the American system, the Motherhouse system, and the Continental system.

In earlier days the American system differed from the Nightingale rather in detail than in principle. The position of the matron is different, and corresponds to a different type of internal organisation in the hospital; but the apprenticeship principle was common to the two systems. What is important for the historian is rather the point at which the American tradition began seriously to diverge from our own. This it did when it yielded pride of place to the schools run on university lines, thereby abandoning the apprenticeship principle. Here surely is rich material for the historian; the new approach was already in full swing by the time of the Goldmark report in the '20s.

Much information has been brought back to this country by nurse visitors who have inquired pretty closely into the results of the system: they have found cause for anxiety about what is happening across the Atlantic. It is certainly of great importance for our own future that the end-results of a system superficially so attractive should be properly assessed. Does it not mean that the bulk of bedside nursing gets delegated to a secondary grade of nurse? Are we right, or are we wrong in seeing the multiplication of university schools on the American model in other parts of the world as a not unmixed blessing? Mrs. Seymer is content to record the approach towards the university as though it were but another step on towards the ultimate goal: "on the whole connections between training schools and universities seem to be multiplying and their cooperation in the teaching of nurses will doubtless be of increasing value." One would feel happier if this advance were chronicled with a more critical pen. The story of nursing since Florence Nightingale cannot be told intelligently without a grasp of the developments which have been going on in the outer world, and an assessment of the manner in which they have obtruded themselves into the handling of nursing questions. A good example of such is the over development of university-ism in America, and its effects upon nursing in the American hospitals. It is sad that it should be accepted uncritically over here.

OPPORTUNITY

We in Britain have now an opportunity unparalleled in the history of nursing. We have the better elements of the old tradition still with us, and we are now about to reverse one, if not both, of the two great mistakes made thirty years ago. Nursing education was then tidied up without the provision of educational funds, and thereby to a large extent stultified: and a single State examination was adopted with scarce a thought given to the alternative policy of control through the training schools. Within the framework of the new Act we have the power to embark upon experiments. Are our minds sufficiently clear to make good use of this opportunity? Or is our whole conception of what is open to us so choked by a firm belief in progress since 1919 that we cannot see that we may have to retrace our steps before we can advance?

THE WORLD'S HEALTH

At the opening of the third World Health Assembly, at Geneva last Monday, Dr. Brock Chisholm, director-general of W.H.O., criticised governments for failing to devote enough of their resources to health services. "What is lacking and what is urgently needed is a greater determination on the part of all national administrations to expand the health services of their countries and thus raise the health standards of their populations . . ."

The Organisation has itself been in difficulties through failure of governments to pay their contributions. Of the 1948 budget, 15·5% is still outstanding, and in 1949 it was necessary to defer final settlement of a loan from the United Nations and to draw on a special UNRRA fund. As it was, expenditure was restricted to $5 million. This first full year of activities is described by Dr. Chisholm in his annual report,[1] issued last week. The year was marked by progressive decentralisation of the Organisation's work; by the end of the year regional offices were functioning in Alexandria for the Eastern Mediterranean region and in New Delhi for the South-East Asia region, while the Pan American Sanitary Bureau in Washington is now serving as the regional office for the Americas, as the first step towards integration of the bureau with W.H.O. A special office was set up for Europe to pave the way for the creation of a regional office in this area.

The former practice of sending field missions to countries has been discontinued; field operations are now carried out, instead, by demonstration teams and short-term consultants. During the year the Organisation concerned itself with only a small number of special fields, such as the control of malaria, tuberculosis, and venereal diseases, and the more general programmes developed more slowly. Among the work carried out by the technical services has been the completion of the *International Pharmacopœia* (announced last month); the sixth revision of the International Lists of Diseases, Injuries, and Causes of Death; expansion of the epidemiological warning system; and progress towards revision of the International Sanitary Conventions.

Coöperation with other bodies is growing. Thus it is expected that this year funds made available under the United Nations programme of technical assistance for economic development will allow of extension of the services to underdeveloped areas, with intensification of health programmes essential for the rehabilitation of agricultural and industrial workers; and last week it was announced that UNICEF was to set aside nearly $6 million to be spent, in conjunction with W.H.O., on improving health conditions in various Asiatic countries.

Dr. Marcolino Gomez Candau (Brazil) has been appointed to the directorship of the division of organisation of public health services. *Dr. Victor Sutter (San Salvador)* has been placed in charge of the division of communicable disease services.

HOSPITAL ADMINISTRATION

PRONOUNCEMENT BY MINISTER

THREE new developments in the administration of the hospital service were announced by Mr. Aneurin Bevan, Minister of Health, when he addressed the annual conference of the Institute of Hospital Administrators, in London on May 5.

Mr. Bevan is reported by the Press Association as saying that a uniform system of hospital accounting—which he hoped they would soon be getting—would pave the way to a system of comparative costing. "This system of comparative costing will show the red light," he said, "and it will be our duty to find out why costs are higher in gross, or higher under any particular heading, in some hospitals. Then the investigation starts." Some of the voluntary hospitals appeared to have had an extraordinary system of non-accountancy, because the Ministry had not been able to discover how they added up or subtracted.

"Further we propose to have—because hospitals vary so much in ages and in their specialties—to have a competent team not consisting only of administrative officials but also men of medical knowledge and with knowledge of hospital administration to visit hospitals. They will establish after an examination on the spot an agreed staff ceiling. After that has been agreed on it will not be possible to exceed that ceiling without consent."

The third development mentioned by Mr. Bevan was an investigation "to find out whether it is possible to have a unit system of costing so that we can have a more refined check still." The Nuffield Trust and King Edward's Hospital Fund were helping towards that end.

ESTIMATES

Mr. Bevan continued: "I have given a pledge for 1950–51 that there will be no exceeding the financial ceiling that has been laid down in the estimates. A lot of foolish things have been said about the Supplementary Estimates, and they have been regarded by some people as pieces of self-evident evidence that the finances of the National Health Service were not under effective control. That is a very silly thing to say because it is not until at least one year's experience has been obtained that it has been possible to find out what the expenses would be. . . . Now our estimates are based on much surer foundations."

"Now" said Mr. Bevan, "we have to show that our administrative machinery is sufficiently gripping to enable us to say with some degree of predictability what the Health Service is likely to cost. Therefore we must have economies in order to have expansions. If the Health Service is to live within its estimates any improvement in any particular part of the service must necessarily come out of the economies in some other part. Next year is an exceedingly important one. If at the end of it we can say—and I am sure we shall—that this vast apparatus is entirely within our management and control we shall have won the most important battle in the development of the service."

Parliament

Amendments to the Medical Bill

WHEN the Medical Bill was considered in Committee in the House of Lords on May 4, Lord WEBB-JOHNSON moved an amendment to clause 2 to avoid the rigid laying down of a period of not less than 12 months for intern service. He hoped this might enable the reform to be put into operation earlier. It would also leave the General Medical Council free discretion in times of difficulty—when dealing with demands for doctors for the Forces, for example—to vary the regulations and the period according to need.

Lord SHEPHERD, speaking for the Government, pointed out that the Goodenough Committee were firmly of the opinion that the period ought to be not less than 12 months. Moreover, he believed that the supporters of Lord Webb-Johnson's amendment did not consider twelve months to be too long but merely wished to solve possible difficulties at the beginning of the scheme, or in times of national stress. In that spirit he was authorised to accept the amendment, and it was agreed to.

Lord Shepherd moved an amendment, which was accepted, enabling the body giving the diploma to indicate the length of service a doctor had to give in medicine, surgery, and midwifery during his intern period.

Lord Shepherd moved a new clause to make it possible for service in a health centre to be counted towards the intern period. He said that the health centre would have to be one of those provided under the relevant National Health Service Acts. It would have to be approved by a licensing body—that was to say, the university or the medical corporation concerned. The service at the centre which might be counted was employment as an assistant in general practice or employment on hospital (outpatient) work there. The General Medical Council were given power to make regulations fixing the amount of service at a health centre which might count towards the intern period. The amendment was agreed to.

On clause 4 Lord Shepherd moved an amendment providing that not only the fully registered medical practitioner but also the practitioner who was provisionally registered should be safeguarded and that anyone falsely professing to be a provisionally registered practitioner should suffer in the same way as a person pretending to be a medical practitioner. The amendment was agreed to.

CONSTITUTION OF THE G.M.C.

On clause 8 (increase of elected members of council. &c.), Lord Shepherd moved an amendment to increase the number of elected members of the G.M.C. from 9 to 11, consisting of 8 from England and Wales, 2 from Scotland, and 1 from Ireland. A subsequent amendment laid down that 1 of the 8 will be a representative from Wales. The amendment was agreed to.

On clause 13 Lord HACKING moved an amendment to increase the number of laymen on the disciplinary committee from 1 to 3. As drafted, the Bill provided for 3 laymen on the *General Council*, which dealt with qualifying examinations, approval of hospitals, the medical curriculum, and the preparation of the *British Pharmacopœia*. What did laymen know about any of these subjects? They did, however, know something about how a doctor should behave—for example, that it was not a good thing for the safety of the public that doctors should frequently get drunk, or take drugs, or misbehave themselves in other ways. Yet upon the disciplinary committee which dealt with these matters the public had only one representative.

Lord MORAN said that doctors felt very strongly about many of the matters that came before the G.M.C., and therefore he felt that those who were in possession of greater detachment, and could dispassionately review these matters, were of great value. For that reason he supported Lord Hacking. Lord SHEPHERD said that the Government had a good deal of sympathy for the object behind the amendment, but they could not accept the full demand which Lord Hacking had made. The disciplinary committee must be predominantly a committee upon which medical experience figured. If Lord Hacking would alter his amendment to allow for two laymen to be appointed the Government would accept it. On the suggestion of Lord LLEWELLIN it was agreed that the amendment should read "at least two" in order that the council could appoint more laymen if they wished to do so. In this form the amendment was accepted.

Lord Llewellin moved an amendment to reduce the quorum of the disciplinary committee from 9 to 5 and then to provide that the committee should not, unless there was a particular reason for so doing, sit at greater strength than 9 members. This, he urged, would provide the G.M.C. with a far more efficient committee to hear those individual cases. Lord NATHAN moved to amend the amendment so that the quorum should include 1 lay member.

Lord SHEPHERD said the Government were willing to accept Lord Llewellin's amendment. While they sympathised with Lord Nathan they did not think that his amendment would give him exactly what he wanted. If one of the laymen happened to be absent from the tribunal either the proceedings would be nullified or the tribunal would cease to sit. However, if Lord Nathan would withdraw his amendment to the amendment, the Government would introduce an amendment on the report stage. Lord Llewellin's amendment was agreed to.

Lord WEBB-JOHNSON moved an amendment to ensure that a conviction should not be arrived at merely by the casting vote of the chairman. He said it seemed desirable in these cases that a decision of such importance should be taken by a majority.

Lord SHEPHERD accepted the amendment, and said that in the event of a tie the doctor would be discharged. Lord WEBB-JOHNSON also moved an amendment to ensure that now that subpœnas could be issued and evidence taken on oath the accused should be entitled to a verdict of "not guilty" when he was not found guilty, and this was accepted.

POWERS OF INSPECTION

On clause 20, Lord MORAN moved an amendment to avoid unnecessary multiplication of inspections of medical schools. It was not, he said, that he believed that such inspections served no useful purpose. On the contrary, during the 25 years he was dean of a medical school he was convinced that these inspections quickened the pulse of a school which had become indolent and led to a review of things left undone. But there was already efficient machinery for securing those benefits. If this clause was passed as drafted the London schools would be inspected by three different bodies—the University Grants Committee, the University of London, and the General Medical Council. There were three bodies governing the policy and that was bound to create confusion. Quite apart from that disadvantage, everybody with educational interests was convinced, he thought, that the hold of London University over its constituent medical schools should be strengthened. That hold would certainly not be strengthened by setting up a rival method of inspection. He suggested that, so far as the University of London and the G.M.C. were concerned, there should be one inspection and not two. That could readily be brought about if the external inspector of London University also represented the G.M.C.

Lord SHEPHERD was able to report that as a result of discussions between representatives of the two bodies an agreement had been arrived at that the university inspectors would act also for the G.M.C. Lord LLEWELLIN pointed out that this agreement might not last permanently. He thought it would be helpful if the matter were placed in the hands of the Government of the day. Lord SHEPHERD said that if Lord Moran would withdraw his amendment he would undertake to look at the matter again before the report stage in the light of what Lord Llewellin had said, and the amendment was by leave withdrawn.

Lord WEBB-JOHNSON moved a new clause to increase from £20 to £500 the penalty imposed by the Medical Act, 1858, on any person falsely pretending to be a registered medical practitioner; and this was agreed to. The committee stage of the Bill was concluded.

of nursing questions. A good example of such is the over development of university-ism in America, and its effects upon nursing in the American hospitals. It is sad that it should be accepted uncritically over here.

OPPORTUNITY

We in Britain have now an opportunity unparalleled in the history of nursing. We have the better elements of the old tradition still with us, and we are now about to reverse one, if not both, of the two great mistakes made thirty years ago. Nursing education was then tidied up without the provision of educational funds, and thereby to a large extent stultified: and a single State examination was adopted with scarce a thought given to the alternative policy of control through the training schools. Within the framework of the new Act we have the power to embark upon experiments. Are our minds sufficiently clear to make good use of this opportunity? Or is our whole conception of what is open to us so choked by a firm belief in progress since 1919 that we cannot see that we may have to retrace our steps before we can advance?

THE WORLD'S HEALTH

At the opening of the third World Health Assembly, at Geneva last Monday, Dr. Brock Chisholm, director-general of W.H.O., criticised governments for failing to devote enough of their resources to health services. "What is lacking and what is urgently needed is a greater determination on the part of all national administrations to expand the health services of their countries and thus raise the health standards of their populations . . ."

The Organisation has itself been in difficulties through failure of governments to pay their contributions. Of the 1948 budget, 15·5% is still outstanding, and in 1949 it was necessary to defer final settlement of a loan from the United Nations and to draw on a special UNRRA fund. As it was, expenditure was restricted to $5 million. This first full year of activities is described by Dr. Chisholm in his annual report,[1] issued last week. The year was marked by progressive decentralisation of the Organisation's work; by the end of the year regional offices were functioning in Alexandria for the Eastern Mediterranean region and in New Delhi for the South-East Asia region, while the Pan American Sanitary Bureau in Washington is now serving as the regional office for the Americas, as the first step towards integration of the bureau with W.H.O. A special office was set up for Europe to pave the way for the creation of a regional office in this area.

The former practice of sending field missions to countries has been discontinued; field operations are now carried out, instead, by demonstration teams and short-term consultants. During the year the Organisation concerned itself with only a small number of special fields, such as the control of malaria, tuberculosis, and venereal diseases, and the more general programmes developed more slowly. Among the work carried out by the technical services has been the completion of the *International Pharmacopœia* (announced last month); the sixth revision of the International Lists of Diseases, Injuries, and Causes of Death; expansion of the epidemiological warning system; and progress towards revision of the International Sanitary Conventions.

Coöperation with other bodies is growing. Thus it is expected that this year funds made available under the United Nations programme of technical assistance for economic development will allow of extension of the services to underdeveloped areas, with intensification of health programmes essential for the rehabilitation of agricultural and industrial workers; and last week it was announced that UNICEF was to set aside nearly $6 million to be spent, in conjunction with W.H.O., on improving health conditions in various Asiatic countries.

Dr. Marcolino Gomez Candau (Brazil) has been appointed to the directorship of the division of organisation of public-health services. Dr. Victor Sutter (San Salvador) has been placed in charge of the division of communicable disease services.

HOSPITAL ADMINISTRATION

PRONOUNCEMENT BY MINISTER

THREE new developments in the administration of the hospital service were announced by Mr. Aneurin Bevan, Minister of Health, when he addressed the annual conference of the Institute of Hospital Administrators, in London on May 5.

Mr. Bevan is reported by the Press Association as saying that a uniform system of hospital accounting—which he hoped they would soon be getting—would pave the way to a system of comparative costing. "This system of comparative costing will show the red light," he said, "and it will be our duty to find out why costs are higher in gross, or higher under any particular heading, in some hospitals. Then the investigation starts." Some of the voluntary hospitals appeared to have had an extraordinary system of non-accountancy, because the Ministry had not been able to discover how they added up or subtracted.

"Further we propose to have—because hospitals vary so much in ages and in their specialties—to have a competent team not consisting only of administrative officials but also men of medical knowledge and with knowledge of hospital administration to visit hospitals. They will establish after an examination on the spot an agreed staff ceiling. After that has been agreed on it will not be possible to exceed that ceiling without consent."

The third development mentioned by Mr. Bevan was an investigation "to find out whether it is possible to have a unit system of costing so that we can have a more refined check still." The Nuffield Trust and King Edward's Hospital Fund were helping towards that end.

ESTIMATES

Mr. Bevan continued: "I have given a pledge for 1950–51 that there will be no exceeding the financial ceiling that has been laid down in the estimates. A lot of foolish things have been said about the Supplementary Estimates, and they have been regarded by some people as pieces of self-evident evidence that the finances of the National Health Service were not under effective control. That is a very silly thing to say because it is not until at least one year's experience has been obtained that it has been possible to find out what the expenses would be. . . . Now our estimates are based on much surer foundations."

"Now" said Mr. Bevan, "we have to show that our administrative machinery is sufficiently equipped to enable us to say with some degree of predictability what the Health Service is likely to cost. Therefore we must have economies in order to have expansions. If the Health Service is to live within its estimates any improvement in any particular part of the service must necessarily come out of the economies in some other part. Next year is an exceedingly important one.' If at the end of it we can say—and I am sure we shall—that this vast apparatus is entirely within our management and control we shall have won the most important battle in the development of the service."

Parliament

Amendments to the Medical Bill

WHEN the Medical Bill was considered in Committee in the House of Lords on May 4, Lord WEBB-JOHNSON moved an amendment to clause 2 to avoid the rigid laying down of a period of not less than 12 months for intern service. He hoped this might enable the reform to be put into operation earlier. It would also leave the General Medical Council free discretion in times of difficulty—when dealing with demands for doctors for the Forces, for example—to vary the regulations and the period according to need.

Lord SHEPHERD, speaking for the Government, pointed out that the Goodenough Committee were firmly of the opinion that the period ought to be not less than 12 months. Moreover, he believed that the supporters of Lord Webb-Johnson's amendment did not consider twelve months to be too long but merely wished to solve possible difficulties at the beginning of the scheme, or in times of national stress. In that spirit he was authorised to accept the amendment, and it was agreed to.

Lord Shepherd moved an amendment, which was accepted, enabling the body giving the diploma to indicate the length of service a doctor had to give in medicine, surgery, and midwifery during his intern period.

Lord Shepherd moved a new clause to make it possible for service in a health centre to be counted towards the intern period. He said that the health centre would have to be one of those provided under the relevant National Health Service Acts. It would have to be approved by a licensing body—that was to say, the university or the medical corporation concerned. The service at the centre which might be counted was employment as an assistant in general practice or employment on hospital (outpatient) work there. The General Medical Council were given power to make regulations fixing the amount of service at a health centre which might count towards the intern period. The amendment was agreed to.

On clause 4 Lord Shepherd moved an amendment providing that not only the fully registered medical practitioner but also the practitioner who was provisionally registered should be safeguarded and that anyone falsely professing to be a provisionally registered practitioner should suffer in the same way as a person pretending to be a medical practitioner. The amendment was agreed to.

CONSTITUTION OF THE G.M.C.

On clause 8 (increase of elected members of council, &c.), Lord Shepherd moved an amendment to increase the number of elected members of the G.M.C. from 9 to 11, consisting of 8 from England and Wales, 2 from Scotland, and 1 from Ireland. A subsequent amendment laid down that 1 of the 8 will be a representative from Wales. The amendment was agreed to.

On clause 13 Lord HACKING moved an amendment to increase the number of laymen on the disciplinary committee from 1 to 3. As drafted, the Bill provided for 3 laymen on the *General Council*, which dealt with qualifying examinations, approval of hospitals, the medical curriculum, and the preparation of the *British Pharmacopœia*. What did laymen know about any of these subjects? They did, however, know something about how a doctor should behave—for example, that it was not a good thing for the safety of the public that doctors should frequently get drunk, or take drugs, or misbehave themselves in other ways. Yet upon the disciplinary committee which dealt with these matters the public had only one representative.

Lord MORAN said that doctors felt very strongly about many of the matters that came before the G.M.C., and therefore he felt that those who were in possession of greater detachment, and could dispassionately review these matters, were of great value. For that reason he supported Lord Hacking. Lord SHEPHERD said that the Government had a good deal of sympathy for the object behind the amendment, but they could not accept the full demand which Lord Hacking had made. The disciplinary committee must be predominantly a committee upon which medical experience figured. If Lord Hacking would alter his amendment to allow for two laymen to be appointed the Government would accept it. On the suggestion of Lord LLEWELLIN it was agreed that the amendment should read "at least two" in order that the council could appoint more laymen if they wished to do so. In this form the amendment was accepted.

Lord Llewellin moved an amendment to reduce the quorum of the disciplinary committee from 9 to 5 and then to provide that the committee should not, unless there was a particular reason for so doing, sit at greater strength than 9 members. This, he urged, would provide the G.M.C. with a far more efficient committee to hear those individual cases. Lord NATHAN moved to amend the amendment so that the quorum should include 1 lay member.

Lord SHEPHERD said the Government were willing to accept Lord Llewellin's amendment. While they sympathised with Lord Nathan they did not think that his amendment would give him exactly what he wanted. If one of the laymen happened to be absent from the tribunal either the proceedings would be nullified or the tribunal would cease to sit. However, if Lord Nathan would withdraw his amendment to the amendment, the Government would introduce an amendment on the report stage. Lord Llewellin's amendment was agreed to.

Lord WEBB-JOHNSON moved an amendment to ensure that a conviction should not be arrived at merely by the casting vote of the chairman. He said it seemed desirable in these cases that a decision of such importance should be taken by a majority.

Lord SHEPHERD accepted the amendment, and said that in the event of a tie the doctor would be discharged. Lord WEBB-JOHNSON also moved an amendment to ensure that now that subpœnas could be issued and evidence taken on oath the accused should be entitled to a verdict of "not guilty" when he was not found guilty, and this was accepted.

POWERS OF INSPECTION

On clause 20, Lord MORAN moved an amendment to avoid unnecessary multiplication of inspections of medical schools. It was not, he said, that he believed that such inspections served no useful purpose. On the contrary, during the 25 years he was dean of a medical school he was convinced that these inspections quickened the pulse of a school which had become indolent and led to a review of things left undone. But there was already efficient machinery for securing those benefits. If this clause was passed as drafted the London schools would be inspected by three different bodies—the University Grants Committee, the University of London, and the General Medical Council. There were three bodies governing the policy and that was bound to create confusion. Quite apart from that disadvantage, everybody with educational interests was convinced, he thought, that the hold of London University over its constituent medical schools should be strengthened. That hold would certainly not be strengthened by setting up a rival method of inspection. He suggested that, so far as the University of London and the G.M.C. were concerned, there should be one inspection and not two. That could readily be brought about if the external inspector of London University also represented the G.M.C.

Lord SHEPHERD was able to report that as a result of discussions between representatives of the two bodies an agreement had been arrived at that the university inspectors would act also for the G.M.C. Lord LLEWELLIN pointed out that this agreement might not last permanently. He thought it would be helpful if the matter were placed in the hands of the Government of the day. Lord SHEPHERD said that if Lord Moran would withdraw his amendment he would undertake to look at the matter again before the report stage in the light of what Lord Llewellin had said, and the amendment was by leave withdrawn.

Lord WEBB-JOHNSON moved a new clause to increase from £20 to £500 the penalty imposed by the Medical Act, 1858, on any person falsely pretending to be a registered medical practitioner; and this was agreed to. The committee stage of the Bill was concluded.

National Assistance Regulations

In the House of Commons on May 3 Dr. EDITH SUMMERSKILL, Minister of National Insurance, moved that the draft National Assistance (Determination of Need) Amendment Regulations, 1950, be approved. She said that the increased purchasing power would go to the least fortunate in the community. The scale for a single adult—there was no sex differentiation—was increased by 2s. and for a married couple by 3s. 6d. With the increase now proposed for children the scale would range from 8s. for a child up to the age of five to 12s. for a child over eleven. The increase in indexed prices was something like 4%, but the increase in the scale was much higher. In March there were rather fewer than 1,200,000 cases, of whom only 700,000 were pensioners.

Dr. Summerskill pointed out that the National Assistance Act placed a duty on the board regarding blind persons and people suffering from pulmonary tuberculosis. The 1948 regulation accordingly included a special scale of allowances for these people. Broadly, that special scale provided an additional 25s. for a husband and wife both of whom were blind or undergoing treatment, and 15s. if one of them was affected. Under these special scales the board was now paying at these rates to about 45,000 blind persons and 25,000 tuberculosis cases. The tuberculosis allowances were a national investment which returned dividends of incalculable value. Not only was the worker enabled to leave his work and obtain treatment as soon as possible, but a source of infection was removed from the family. The new regulations would maintain the existing difference between the new scale and the old. The ultimate cost of these new proposals would be something in the order of £10 million. The regulations were agreed to.

QUESTION TIME

Consumption of Milk

Mr. MAURICE WEBB, Minister of Food, replying to a question, stated that it was estimated that 1,015,000,000 gallons of milk would be consumed this year by private purchasers, apart, of course, from the Welfare Scheme. The corresponding figure for last year, when for a great part of the year the non-priority allowance varied between two and three pints a week, was about 980,000,000 gallons. It would not be practicable to have a scheme for selling a fixed allowance to all consumers at a subsidised price and any balance at a higher price.

Petrol Tax and Doctors' Remuneration

Dr. CHARLES HILL asked the Minister of Health if he was aware that the increase in taxation on petrol would result in a reduction in net remuneration of general practitioners in the National Health Service, whose State remuneration was gross, and inclusive of practice expenses; and whether he would arrange for the appropriate addition to be made to the central pool for general practitioners' remuneration, so as to maintain the net remuneration at the level laid down by him.—Mr. ARTHUR BLENKINSOP replied: I cannot regard the imposition of a new tax as constituting grounds for an addition to remuneration.

Medical Students and Risk of Infection

Mr. J. H. MCKIE asked the Secretary of State for Scotland whether, in view of what happened in the recent smallpox outbreak in Glasgow, he would ensure that in future no medical student was exposed to unnecessary risk in fever cases.—Miss MARGARET HERBISON replied: Medical authorities are fully conscious of the need to control and prevent the spread of infection, and I am assured that all practicable measures are taken to reduce to a minimum the inevitable risks which medical students, like doctors and nurses, must take in their contacts with patients.

Results of Vaccination

Mr. T. G. GALBRAITH asked the Secretary of State for Scotland how many of the 14 patients recovering from smallpox had ever been vaccinated.—Miss HERBISON replied: All the patients who are recovering from smallpox had been successfully vaccinated either in infancy or later. The number concerned is 12, the diagnosis of smallpox not having been confirmed in the other 3 patients who are recovering.

Mr. GALBRAITH asked the Secretary of State for Scotland what was the percentage of infants who were vaccinated during the past twelve months up to the latest convenient date; and what was the yearly average of infants vaccinated over the 10 years previous to this.—Miss HERBISON replied: In the year ended Dec. 31, 1949, some 18% of the infants under one year of age are known to have been vaccinated, but the figures are not complete. For the ten years 1938-47 the yearly average percentage of infants vaccinated was 53

Mr. GALBRAITH: In view of the fact that all those who died of smallpox had not been successfully vaccinated what does the department intend to do to halt this decrease in the number of young people who are now being vaccinated?

Miss HERBISON: The figure of 18% is by no means the average figure for 1949. The returns from local health authorities showed a figure of 18%, but there is discussion going on now between the local health authorities and the general practitioners about their returns which have not yet been made. We hope that at the meeting to be held in the near future some arrangements will be made and the returns will come in. Until they do come in we cannot get the correct percentage. As regards future action, we must wait until we have the complete figures, although we realise the seriousness of the position and are hoping that the recent smallpox scare will make the public realise how important this is. Every step will be taken by the department, as in the case of diphtheria immunisation, to have children vaccinated.

Waiting-list for Hearing-aids

Replying to a question Mr. BEVAN stated that the size of the waiting-list for hearing-aids amounts to about 86,000. Distribution facilities were being increased, and would be further increased as circumstances allowed; but he was not prepared to adopt arrangements which did not include adequate instruction in the use of deaf-aids.

Colonial Medical Service

Commander A. H. P. NOBLE asked the Secretary of State for the Colonies what was the number of vacancies existing for medical officers in the Colonial Medical Service.—Mr. JAMES GRIFFITHS replied: There are 213 vacancies for medical officers in the Colonial Medical Service.

Suppression of Dust in Mines

Dr. BARNETT STROSS asked the Minister of Fuel and Power what use had been made of chemical detergents in the suppression of dust in coalmines; and how far they had been proved to be of value.—Mr. P. NOEL-BAKER replied: The use of chemical detergents as wetting agents in the suppression of dust is under experimental trial at many coalmines. They are giving promising results, particularly in the consolidation of deposits of dry dust on mine roadways and in mines where the underground conditions make it desirable to use as little water as possible. The National Coal Board and H.M. Inspectors of Mines continue to give close attention to the matter.

Coroners' Powers

Mr. ANTHONY MARLOWE asked the Home Secretary how many coroners had no legal qualification; under what authority they admitted hearsay evidence; in what circumstances they might exclude the press from an inquest or hold an inquest in camera; whether they were required to make and preserve records of evidence given before them; and what steps were taken to ensure uniformity of procedure in coroners' courts.—Mr. CHUTER EDE replied: The information asked for in the first part of the question is not available. The coroner's discretion as to what evidence should be admitted at an inquest is vested in him by Common Law. While a coroner's court is ordinarily open to the public the High Court confirmed in 1827 that the coroner has a discretion under the Common Law to hold an inquest in private for reasons which appear to him necessary and proper. Coroners are by statute required to take depositions in cases of murder and manslaughter. It is generally accepted that they should keep these records and should also keep records of the evidence in other cases. Coroners are independent judicial officers who are not answerable to any Government department, but are bound by the Common Law and the provisions of the relevant Acts and rules made thereunder.

Mr. MARLOWE: Does not the Minister think that all this discloses a rather unsatisfactory condition in coroners' courts and that it is time legislation was introduced to secure some form of uniformity? In view of his answer last week [1] that his would arouse controversy, does he not think that each f these suggestions could pass through this House without ny political controversy? Mr. EDE: I am not sure that ave "noncontroversial" matters would not develop into ontroversy.

---

[1] See *Lancet*, May 6, p 876.

Mr. LESLIE HALE: In view of the fact that no verdict of a oroner's inquest can be mentioned at subsequent proceedings, and that it is now general to adjourn pending proceedings, does he think that coroners' courts now serve any purpose to the community?

Mr. EDE: Oh yes, I think they have their uses.

Earl WINTERTON: Is the Minister aware that there is a very considerable depth of feeling, legal and otherwise, that this whole matter needs review by this House? Mr. EDE: I think it is a matter which, when there is time, might advantageously be considered.

Reciprocal Arrangements for National Insurance

Replying to a question, Dr. EDITH SUMMERSKILL, Minister of National Insurance, stated that reciprocal arrangements were in operation with Northern Ireland and the Isle of Man for national insurance, industrial injuries insurance, and family allowances, with the Irish Republic for sickness, maternity, and unemployment benefits and for the insurance of seamen, with New Zealand for family allowances, and with France for national insurance and industrial injuries insurance. It was hoped that a multilateral agreement on social security, signed by the five Brussels Treaty Powers, would be ratified by this country next month. Negotiations were taking place for further agreements with Australia, New Zealand, the Irish Republic, France, Belgium, the Netherlands, Luxembourg, and Denmark.

Hospital Accounts

In answer to a question, Mr. A. BEVAN stated that, as required by the National Health Service Act, summary hospital accounts would be presented to Parliament annually and the first such account would be available shortly.

Air Commodore A. V. HARVEY: Would it not be better for all hospitals to publish their own accounts, which would lead to greater efficiency and understanding among the staffs? Mr. BEVAN: If hospitals published accounts to the public before they were published for the benefit of the House of Commons, it would be a breach of privilege. Mr. GEOFFREY COOPER: Would the Minister consider making the fullest financial information available to hospital management committees? They cannot carry out their job unless they have the fullest access to financial details. Mr. BEVAN: I should be astonished to learn that hospital management committees do not know of their own accounts. That is entirely different from the public having access to the accounts before they are presented to Parliament.

Replying to Sir RALPH GLYN, Mr. BEVAN said that in the last few weeks he had addressed conferences of chairmen of boards of governors of teaching hospitals, regional hospital boards, and hospital management committees at which he had reported that the Ministry were now issuing standard accounts. Mr. R. S. HUDSON: When the accounts have been published for the benefit of Parliament, will the accounts of local hospitals be available locally? Mr. BEVAN: I will look into it, but I see no special reason why they should not be, because I am hoping to encourage local hospitals to hold annual open meetings at which they can discuss their affairs.

Mass X-ray Examination of School-children

Mr. ARTHUR LEWIS asked the Minister if he would arrange for mass X-ray units to carry out a regular examination of all school-children.—Mr. BEVAN replied: I am advised that mass radiography can most usefully be applied to adults, but so far as possible examinations of children, particularly at school-leaving age, are also undertaken.

Reciprocal Medical Services

Sir WALDRON SMITHERS asked the Minister, in view of the fact that free health services were extended to foreigners coming to this country, with which countries he had now arranged for the giving of reciprocal facilities.—Mr. BEVAN replied: A convention on social and medical assistance with Belgium, France, Luxembourg, and the Netherlands has been signed and awaits ratification. Another agreement on details has also been signed. The arrangement is that nationals of any one of these countries, who are without sufficient means and who lawfully reside in the territories of another, can benefit by the medical and social legislation of the country in which they are.

In England Now

A Running Commentary by Peripatetic Correspondents

"PATRIOTIC PÆDIATRIC REGISTRARS MOVE ON ADAM STREET. RIOTS IN THE STRAND."

Newspaper headlines? Well, not quite, but the peripat last week (p. 877) who said "There is something in the practice of pædiatrics which drives out the nobler virtues" ought to have visited Windermere in his wanderings. The annual meeting of the British Pædiatric Association recently held there was far from lacking in the nobler virtues, if friendliness, encouragement of juniors, and simplicity of outlook, with the welfare of the child as the underlying interest of all present, are worthy of being called noble. The timing of his alleged telegram and of his communication are both suspicious. Can it be that he failed to secure election to membership of the B.P.A.? If an intense concern about the younger members of the community is not patriotism there is something wrong with terminology. The reasons given for the fall in infant mortality range from better feeding to the disappearance of horses from the streets; it is seldom that anyone pats the pædiatrician on the back. And now this peripat expresses doubt whether the coefficient of patriotism is high among us. It's almost as bad as the House of Lords. Perhaps Lord V—t is a secret peripat? Hoots, toots, as Sir Robert Hutchison used to say when someone made a stupid diagnosis. Our pædiatric registrars are patriotic to a man. Of course it *is* a difficult word for the uneducated. There was that dreadful year when the menu card called us "Pæderastic." Fortunately women had not been admitted to membership then. But patriotic!—You only have to look at the name of the Association.

* * *

So far, in the journals or standard textbooks, I have seen no mention of Steinharger disease, which occurs in two forms, acute and chronic. Acute attacks used to be quite common, especially around Hogmanay, but in these days of heavy taxation a classical case is becoming a rarity. I am therefore describing an epidemic which occurred in Germany in recent years, even though the data are incomplete.

Just after the surrender of the German Army it was reported to higher authority that, in a group of villages, one of which was called Steinharger, not far from the city of Bielefeld, there were a large number of gin factories. The inhabitants were said to be running them at high pressure and selling the product on the black market, chiefly to their fellow villagers, who were suffering terribly as a result and were causing a serious annoyance to the Allied troops, who were trying to live a quiet life and forget all the violence and other unpleasantnesses of war.

A battalion of troops was therefore sent to the district to garrison the villages and prevent the liquor being produced. Meanwhile, the brass-hats devised plans to ensure that, when the factories were restarted, the finished product would be directed through the proper channels—namely, the digestive channels of the officers, W.O.s, and sergeants of the B.L.A.

Unfortunately, when the battalion arrived all ranks became unconscious within a few hours, and the manufacture of the liquor proceeded at a steadily increasing rate as neighbouring units discovered that it was to be had for a cigarette a bottle.

When the garrison of Steinharger had failed to indent for its liquor ration for the second month in succession, it was realised that something was really wrong. A staff officer was sent to investigate. He returned some days later with his vehicle badly damaged, looking very ill. In due course he made his report.

As a result of this report a new battalion (shall we call them the Loamshires?) was detailed to take over the garrison duties and to assist the present garrison (the Blankshires?) to bury their dead, evacuate their sick, and transport the survivors to quarters where they might rest and recuperate. The C.O. of the Loamshires was also instructed to convey to his opposite number in the Blankshires the compliments of a certain very high officer, together with a bowler hat.

Unfortunately, on their arrival, the Loamshires were unable to identify any individual member of the Blankshires; nor could they distinguish the dead from the dying. So they loaded the Blankshires into the Blankshires' transport, together with such articles of the Blankshires' equipment as the Loamshires had no need for, towed the whole unit to a nearby bit of waste land, and left it there.

Then they all returned to their new quarters and were almost immediately struck down. Within 3 hours, no-one was conscious except one Irishman, who was roaring round in a manic state looking vainly for someone to fight. So then the Loamshires were replaced and several more units took their turns, with similar results.

Between the parties, the staff had been working on the "*Steinharger Plan*," which would render a garrison unnecessary. With the coöperation of the Military Government they rationed the raw materials to the factories of the Steinharger Group and demanded such a vast quantity of the finished product (containing 25% ethyl alcohol) that they were sure that the manufacturers would soon exhaust their stocks and then they could institute a rigid system of control with each potato and each spoonful of gin accounted for in triplicate.

In those happy days German manufacturers never dreamt of disobeying an order from a high military authority. So they produced quarts out of pint pots week after week, and yet still had plenty left for their friends at an exorbitant price. How this was done has never been divulged, but some economists contend that the phenomenon was in some way connected with the high price of potatoes on the neighbouring black market at that time.

Thus we have a series of localised, independent yet connected outbreaks of acute Steinharger disease in comparable communities of 500–800 healthy young adult males. Oddly enough, though a good many doctors were present throughout the epidemics, none of them has been reported, and this communication has had to be based entirely on information from non-medical sources. The explanation may be that in each epidemic the doctor was among the first to succumb. And after this disease there is always a total amnesia covering the period of the illness. It says a lot for the spirit of these doctors that, though each must have known what was in store for him when he arrived in the Steinharger area, there is no record of any doctor trying to avoid such a posting. On the contrary, the local A.D.M.S. received many offers from medical men willing to fight the Scourge of Steinharger.

* * *

I am surprised that none of the writers replying to Dr. Learoyd's "carnage on the roads" article has expanded his "small psychological point . . . which is the basis of a big proportion of road accidents."

This "display of superiority" is the manifestation in motorists of a syndrome which is of growing psychiatric interest elsewhere. The possession of a motor-car has an effect on an unstable personality exactly like that which comes from the possession of a gun, a uniform, or political office. It insulates him from personal contacts, it gives him a sense of power and exhilaration, and it provides a platform for psychopathic gestures against other people. If one is aggressive as a pedestrian and jostles people, or shouts abuse at those who don't move, one is faced with the possibility of remonstrance—on wheels, one is insulated. A windscreen is a very good Iron Curtain. How far this dissociation and release can go was illustrated, for me at least, by a professional colleague of mild deportment who, when rudely overtaken, let go of the wheel, placed his thumbs in the corners of his mouth, prolonged that orifice in the direction of his ears, and stuck out his tongue. For that matter, I myself have on two occasions made fat bacon at other motorists, a gesture typical of small boys and delegates to the League of Nations. Insulation, power, and a platform. One finds them in a car or in becoming a national leader. We might make a few candidates for office drive from Land's End to John o' Groats under unobtrusive photographic observation.

Letters to the Editor

SYMPATHECTOMY IN HYPERTENSION

SIR,—Physicians frequently adopt a rather gloomy attitude towards surgical therapy, and Professor Platt and Dr. Stanbury, in their article of April 8, are no exception. Their bland assurance that the better results claimed by others may be due to fundamental misconceptions may be somewhat misleading. Could it possibly be that Platt and Stanbury themselves have made the wrong approach?

It can never be too strongly stated that a small, rapidly performed, subdiaphragmatic denervation is sufficient for symptomatic relief in hypertension, and that it is both unnecessary and very risky to expose the advanced brittle type of hypertensive to more. One would have thought that this fundamental fact was now well known, and that the pursuit of the mirage of normal tension in such cases was long abandoned. At the same time this symptomatic relief is one of the greatest blessings conferred by sympathectomy, and the mode of its production is one that Professor Platt might profitably consider, more particularly because the relief is certainly not functional and non-specific.

His criteria for operability in the early case—always a difficult decision, even with many years' experience—are far in excess of those generally allowed in other reports. This applies particularly to the high diastolic figure of 120 mm. Hg as a necessary minimum prerequisite to operation. Careful consideration of the patient's symptoms and his family history will be of far greater importance than any such arbitrary level. Symptoms determine the operability—one does not operate in their absence, but one frequently operates for their alleviation alone. This is a simple but *well-proven* axiom. The early case suffering the ill effects of hypertension can have his blood-pressure reduced to normal and his symptoms relieved. In the late case symptomatic relief is all that one can expect.

Professor Platt's paper, with its grim operative mortalities, is an example of what can happen when the right operation is applied to the wrong person. Professor Boyd's well-known skill would have been better applied to less damaged cases. That simple little maxim—the small operation for the late case, the large operation for the early one—is worth considering in the sphere of hypertensive sympathectomy.

I find myself in agreement with the views expressed in the letters of Professor Wells and Mr. Shucksmith (April 22). My experience of these operations now extends over six years and over a hundred cases.

Only 3 have died, and only 1 died within six months of the operation. In many cases symptomatic relief and abolition of visceral damage (the latter largely ignored in Platt's paper) was all that was sought. In nearly half the cases a reduction to normal or near-normal was aimed at, generally by the classical Smithwick procedure. The results are very satisfactory in both groups, and certainly merit continuation of the procedure, at least until the introduction of some adequate and simple medical therapy. This was originally reported in 1946,[1] and a further article is being prepared.

My anæsthetist colleagues would like me to comment on the blood-pressure chart exhibited by Professor Platt and Dr. Stanbury to demonstrate the analeptic action of 'Methedrine' in such cases. We have been using this drug to maintain the blood-pressure unshaken during operation and for 36 hours afterwards for over four years. Indeed, I thought this was a widely established routine, as it should be. It is regrettable that Professor Platt did not discover its value until late in his series. No oubt with this and some further modifications in his pproach to the problem, his next series will be more appily in keeping with general world statistics.

AMNIOTIC GRAFTS IN CHRONIC SKIN ULCERATION

SIR,—The interesting paper last week by Mr. Troensegaard-Hansen suggests by its title a basic misconception. The word graft means "transplanted living tissue," and it is quite certain that amnion which has been "boiled for seven minutes in normal saline" is in no sense living. The use of amnion, boiled or dried, to repair dural defects or to enclose repaired tendons offers no support for Mr. Troensegaard-Hansen's ingenuous assumption that this membrane "possesses some specific healing power." Neurosurgeons also use 'Tantalum' plates, and other surgeons use sterile 'Cellophane'; but these, though inert, are certainly without "specific healing power." Amniotic membrane was at one time widely used for conjunctival lesions, such as lime burns, but ophthalmologists have now generally abandoned it in favour of better methods that involve the use of living tissues.

The good results which Mr. Troensegaard-Hansen reports are encouraging, but they are notably similar to those claimed by others for the Bunyan-Stannard envelope and for aluminium foil, though neither of these materials have ever been miscalled a "graft." It would, however, be a pity if these useful methods excluded the proper application of autogenous skin, either as a free graft or as a cross-leg flap. This, in conjunction with the necessary sympathetic or vein surgery, must remain the best method for the worst ulcers, and is often the only procedure likely to command success.

The Queen Victoria Hospital,
East Grinstead, Sussex. C. R. MCLAUGHLIN.

P.A.S.

SIR,—In view of recent advertisements in the medical press for a newly introduced brand of sodium *p*-aminosalicylate, it may be opportune to summarise some facts about the various forms of P.A.S. available for the treatment of tuberculosis.

This drug is obtainable in a high state of purity in the form of the free acid and its sodium salt. For the guidance of clinical workers it should be stated that the sodium salt is not an innovation of recent months, but has been in use in this country for two to three years. It is, in fact, the form of P.A.S. most widely used in Great Britain and various other countries.

Little has so far been published on the toxic effects of long-continued administration in the high dosage employed, nor does the literature indicate that *Mycobacterium tuberculosis* is unable to develop strains resistant to the drug.[1] Toxic effects believed to be due to a disturbance of sodium-potassium levels have recently been observed in a number of cases following administration of the drug over a long period in the form of its sodium salt.[2] Accordingly, until more clinical experience has been reported, the sodium salt should be used with discretion.

On the positive side, clinical literature indicates that the drug has value as a tuberculostatic agent, particularly when given in combination with streptomycin.[3]

DEOXYCORTONE WITH ASCORBIC ACID IN MENTAL DISORDER

SIR,—The use of deoxycortone with ascorbic acid in psychiatric practice may well be widely promoted by the deduction of Dr. Cranswick and Mr. Hall (March 25) of "a close correlation between the reaction of patients to this form of treatment and to electro-convulsive therapy" in the experiment they describe. (One presumes this correlation is deduced from more than the two cases they actually state were given E.C.T. during the investigation "to compare the clinical and biochemical changes.")

It might be assumed that the benefits of E.C.T. may be obtained by this method without the convulsion, memory disturbance, and so forth, which would indeed be an advance; and I therefore feel that it is urgently necessary to record, briefly, entirely contrary results, obtained in December, 1949, with this combination of substances.

The trial by Cranswick and Hall consisted in injecting a number of individuals with the combination and noting any effects. Here, in 9 subjects, of whom 8 were selected (accurately as it transpired) as likely to benefit from E.C.T., the reactions to deoxycortone with ascorbic acid were compared with those to distilled water similarly injected and with those to E.C.T. For the purposes of a letter the following results may be sufficiently illustrative:

1. A middle-aged Polish man, admitted following a determined, mutilating, suicidal attempt, in depressive stupor, inaccessible, immobile, requiring tube-feeding and continuous nursing, remained absolutely unchanged over five days while given daily treatments thrice with deoxycortone and ascorbic acid, according to Lewin and Wassén's technique. He was then given E.C.T. with immediate improvement and ensuing remission.

2. A middle-aged man in his second attack of depression, retarded, with mask-like face, pessimistic, self-reproaching, remained unchanged over five days while given daily treatment thrice with deoxycortone and ascorbic acid and once with distilled water. He was then given E.C.T., responding immediately with subsequent remission.

The pitfalls in assessing therapies in psychiatry are notorious, and it is doubtful if transitory emotional and behavioural reactions of a miscellaneous series of cases to one or a few injections can lead even to any "suggestive" conclusions.

How potent suggestion can be and how easy it might be to make a case for distilled water as meriting "cautious systematic trials," for which Cranswick and Hall plead on behalf of deoxycortone and ascorbic acid, is clear from the example of a long-standing paranoid schizophrenic. She said she was suffering with "Bright's disease, coronary thrombosis, pulmonary T.B., hypertension, and heart block" and had to be given the distilled-water injections with more than verbal persuasion, opposing it as an attempt to put her out of the way. By the next day she was remarkably changed, up and out of bed, friendly, helping in the ward work, and, though presenting the same delusions, subjectively better. Her description was that after the injections she felt worn out and faint with pain over her heart, later in the day becoming aware of distinct benefit.

Almost any treatment, provided that it can be coupled with enthusiasm, will bring brief improvements and occasional successes in psychiatric cases, and there is nothing in Cranswick and Hall's uncontrolled experiments that does not exemplify this or that indicates any specific benefits with deoxycortone and ascorbic acid.

Deoxycortone is expensive (5s. per 5 mg. ampoule) and not free from dangers, and it will be a pity if mental-hospital funds are diverted on any large scale to its purchase with so little justification.

Netherne Hospital,
Coulsdon, Surrey. HAROLD BOURNE.

indeed, the outlook is grim. This method, in my experience, is suitable for only a small proportion of private patients, and is, in effect, null and void for psychiatric outpatients. When sufferers from chronic anxiety, however, seek help, they seem to deserve more dextrous consideration than can be provided by common-sense clichés or irrelevant physical methods in psychiatry; and this holds, despite the fact that only a minority of these invalids are able to benefit from profound psychological interference.

Subacute episodes, arising in patients with an established background of mild persisting anxiety, are common events in psychiatric practice. Competent management of these cases requires a skilled technique founded on special knowledge. In many of these instances, given adequate handling, recovery can be achieved, and—even more important—the effects of anxiety-dictated outbursts, which bring such material and spiritual distress in their train, avoided. It is in this sphere, perhaps, that the medical psychologist makes his practical contribution to therapeutics in general. Total psychotherapy elicits new facts, and this is of immense importance; but the significance of the information so obtained is of interest only to those with special equipment.

Practitioners of every variant have a common concern in the results of treatment; this is, perhaps, the most secure basis for a modus vivendi between a psychotherapist and his colleagues. Protestants against psychiatric departments being converted into "therapeutic dustbins" have, to my knowledge, waxed eloquent for a quarter of a century; there is still no sign of a second Reformation.

London, W.1. MURDO MACKENZIE.

PURIFICATION OF VACCINE LYMPH

SIR,—Dr. McClean's article[1] and the subsequent correspondence[2] prompts me to add my own experience in vaccine-lymph production, with emphasis on methods of reducing the bacterial count.

For some years none of the methods in use to achieve this result gave me satisfaction. These included the use of clove-oil, chloroform, and phenol. The first was almost useless, and the second in our experience difficult, time-consuming, and definitely destructive of potency of the lymph. Phenol, 0·5% with glycerin-saline, proved useful, but still failed to reduce the count sufficiently unless allowed to act over a long period of time. I finally devised and used a method based on a suggestion made to me in 1934 by Dr. James Craigie, who at the time was working in the Connaught laboratories of the University of Toronto. This method proved so completely satisfactory that it was incorporated into routine usage in the Bacteriological Institute, Hong-Kong, and was still our standard practice until my retirement in 1947. I made a brief report of the method to the Congress of the Far Eastern Association of Tropical Medicine at Hanoi in 1938.[3]

Briefly, this method consists in the addition of 2% anæsthetic ether to the fully prepared and diluted lymph. The mixture is vigorously shaken for a few minutes and placed in the refrigerator for 10–14 days. The bacterial count after this period will invariably prove to be somewhere in the region of 2000 per ml. or less. There is no loss of potency. At first we used to remove the ether by bubbling air through the lymph, but found that this was unnecessary; instead we plugged the container with a cotton plug and allowed normal evaporation to take place.

Anything simpler than this method would be hard to imagine, and I would be most interested to hear of other workers' experience with it.

Barbados, British West Indies. A. V. GREAVES.

GENERAL PRACTICE TODAY

SIR,—I was surprised and pained by the number of your correspondents who interpreted Dr. Collings's report as a slap in the face for British general practice. No-one can yet tell whether or not it surveyed a representative sample. I myself, since I have decided to return to England to take up general practice, sincerely hope it was not, but I cannot suppress an inner fear that it may be.

Anyone who has worked in an industrial practice such as Dr. Collings describes with Dickensian vividness, as did one of my brothers, will accept his report. Those who regard him as unsympathetic to British general practitioners can only have gained such an impression by dipping into the report here and there to read his more lurid examples of practices encountered.

Canadian and American doctors have lost much of the British general practitioner's skill in human relationships and ability to help in family problems affecting the patient; but that seems no reason for us to sneer at the first-class organisation and equipment of the average Canadian doctor's "office." Clerical and technical assistance, with facilities for simple investigations, such as blood-counts and erythrocyte-sedimentation rates, are the rule rather than the exception.

The strenuously maintained medical myth that a salaried person cannot do his work conscientiously is preventing the most logical solution to the problem of over-large lists. This idea seems absolutely fantastic to the vast numbers of competent, conscientious, professional men who earn their income by salary in this modern world. As far as the doctor himself is concerned, the present system of payment seems to perpetuate most of the disadvantages of the old system, while I very much doubt that it squeezes any additional public service from him. The quality of service rendered by a doctor in a given environment is influenced solely by his conscience, training, and sensitivity to public opinion—roughly in that order.

Department of Bacteriology,
University of Saskatchewan,
Saskatoon, Canada.

A. G. RICHARDS.

SIR,—Until it is decided what constitutes a G.P.'s work and how many patients he can adequately treat, we shall get nowhere. At one end of the scale are the men with small practices, suffering financial hardship but trying to practise good medicine with as many investigations as they can; at the other end are the four-thousand odd being given the best service that can be expected from overworked and harassed doctors. Quality brings bankruptcy: quantity does have some financial reward.

Mr. Somerville Hastings (May 6) would like to see a full-time salaried service—*after* health centres are established, I hope. Where are our promised health centres with the equipment we need? At hospital, porters, nurses, sisters are there with a specified task. The doctors take one history whilst other patients undress. A clinical examination made, the appropriate investigation is then ordered. Nurses clean the instruments used or attend to dressings. Many persons take part in giving service which is expected of the G.P. single-handed. No hospital doctor pays for his own equipment, clerical assistance, or nursing. Neither does he maintain a car for the sake of his patients; there are ambulances. He does not pay for electricity, heating, cleaning, telephones, postage on pathological specimens, or stationery. All these are essential for five hundred or four thousand patients.

There has been a big revolution in our conception of diagnosis and treatment for the individual patient. The old surgery and waiting-room are things of the past. We cannot work without the health centre and its

tendant equipment and assistants. If we G.P.s will only ut our house in order and demand this, we might begin get a solution to our difficulties.

Wigmore, Kent. GORDON STRONG.

SIR,—"Ex-Student's" criticisms last week of his own medical education point to some of the difficulties of the process. That it should have led him to state that "there seems no way in which the general practitioner . . can get access to laboratory facilities which would put his work on a scientific basis" is greatly to be deplored. It is the kind of sentence with great implications which is too readily acceptable. There is no difference in kind between hearing râles through a stethoscope and counting white blood-cells through a microscope. They are both observations of certain degrees of accuracy, though neither is as accurate an observation as measuring the circumference of a limb with a tape-measure. Scientific medicine is the treatment of such observations by the scientific method, and is therefore by no means beholden to the laboratory alone.

In saying this, I do not in the least wish to diminish the point your correspondent had in mind—namely, that laboratory facilities should be available in general practice.

Dunn Laboratories, St. Bartholomew's Hospital, London, E.C.1. C. J. LONGLAND.

"VARICOSE ULCER"

SIR,—One is rarely afforded the opportunity of criticising two articles in a single issue of your journal, but the papers by Dr. Bull and Dr. Fraser (myxœdema from resorcinol ointment) and Mr. Troensegaard-Hansen (amniotic grafts), both of May 6, contain two small related items which provide an apt demonstration of a confusion of clinical thought which is all too common.

Boyd[1] has said that surgery may be divided into two parts—before John Hunter and after. In the same way, ulcers of the leg may be divided into two groups—varicose ulcers and others, or, as some of us like to think, before Dickson Wright and after. Varicose ulcer is a simple, clear-cut entity. It is due to circulatory stasis and tissue malnutrition caused by the back-pressure within varicose veins (and by "varicose veins" I mean not just "visible veins," but veins with an incompetent valve, commonly the saphenofemoral, between the superficial and deep venous systems of the lower limb). Dickson Wright,[2] who showed this clearly in 1931, also forcibly demonstrated that true varicose ulcers can be healed by properly applied pressure bandages with the patients ambulatory and performing their normal work—not laid up in bed for ten weeks. A varicose ulcer will heal with the patient confined strictly to bed, the foot of which is raised.

But what of the other group—the non-varicose ulcers? Here we have a different story. The causes are almost as numerous as the ulcers themselves, and they must be treated according to their lights, if the impenetrable gloom which surrounds them is to be illuminated by a shaft of epithelium. Dr. Bull and Dr. Fraser, in case 3, describe a "left white leg which soon became complicated by a varicose ulcer." Had they said "complicated by a post-thrombotic gravitational ulcer," it would have been more in keeping with the high standard of their carefully documented paper. Mr. Troensegaard-Hansen is as bad an offender. Cases 1 and 2 had "intermittent claudication with varicose ulceration"; surely the ulcers were due to the poor arterial blood-supply, not venous back-pressure. Case 3 had diabetic gangrene of the toe, as well as his "varicose ulcer"—this speaks for itself.

My point, Sir, is simply this: it is surely a retrograde step to advise amnion grafting and ten weeks' rest in bed for varicose ulcers (in the true sense) and to ignore the straightforward ambulatory treatment, during which the harder the patients work the better. This is not to say that I do not welcome Mr. Troensegaard-Hansen's work on amnion grafting, which may, in time, be shown to have a valuable place in the treatment of chronic non-varicose leg ulceration, which often fails to respond to ambulatory treatment. But we must get away from the promiscuity of diagnosis in which all ulcers of the leg are haphazardly labelled "varicose" according to their site rather than their underlying pathology.

Varicose Vein Clinic, Metropolitan Hospital, London, E.8. S. M. RIVLIN.

ANEURINE IN CARDIOLOGY

SIR,—After ten years' experience with aneurine (vitamin B_1) in the treatment of cardiac conditions I have come to recognise certain indications and contra-indications for its use.

Indications

(1) Extrasystoles of all three types, such as are caused by increasing age, organic heart-disease, tobacco, over-exertion, dyspepsia, generalised infections, and digitalis.

(2) Auriculo-ventricular block with lengthened P–R interval.

(3) Simple tachycardia with lowered exercise tolerance—e.g., "flabby heart" as in mild post-rheumatism cases, neurocirculatory asthenia, and heart-failure.

(4) Paroxysmal tachycardia associated with mitral stenosis.

All these conditions respond slowly but surely to aneurine 9 mg. by mouth daily. If, moreover, the patient has hypotension and a pulse-pressure less than 40 mm. Hg, a good result will be obtained within three months, but maintenance doses of 1·5–3 mg. daily seem advisable for years. Chronic alcoholics respond only to intramuscular injections—e.g., 3 mg. on alternate days. Large doses—e.g., 100 mg. t.i.d.—seem to be no more effective than small ones and can cause trouble.

Contra-indications

Only very small doses of aneurine should be given in cases of hypertension with a pulse-pressure more than 60 mm. Hg—i.e., not more than 3 mg. a day for the first week. Special care should be taken to avoid giving aneurine with riboflavine. I have seen severe anginal pain and even slight coronary thromboses follow a few days' sense of well-being as a result of high initial doses (more than 90 mg. a day) in such cases.

Aneurine should not be given within four weeks of a patient's changing to a much more bracing atmosphere.

Random Cases

The following two cases illustrate typically the value of aneurine.

CASE 1.—A woman, aged 23, had had rheumatic fever at the age of 18, when she had been confined to bed for six months. Since then she had been well but not energetic. During the past year she had noticed a gradual decrease in exercise tolerance, having had to give up tennis mid-season, and now being very tired before her day's work was done. Her heart was slightly enlarged, with soft hæmic murmurs, no organic lesions, no anæmia, and blood-pressure 100/70 mm. Hg. Simple tachycardia was diagnosed. She was given 'Bemax' 1/2 oz. daily. Four months later she could play tennis for 2 or 3 hours and work after it. Her heart was still slightly enlarged, but the murmurs had disappeared. Her blood-pressure was 120/65, and her pulse-rate at rest 65. She continued to take bemax, and seven years later she was well, and had given birth to two babies by the natural passages, without any ill effects.

CASE 2.—A man, aged 65, could walk only 50 yards on the level before the onset of dyspnœa and pain suggesting coronary atheroma. He had first had dyspnœa at the age of 46. He had auricular extrasystoles with irregularly dropped pulse beats. His blood-pressure was 130/100. Aneurine 3 mg. t.i.d. was prescribed. Three months later his pulse was regular, he had no extrasystoles, he could walk three miles or more without distress, and his blood-pressure was 150/90. He continued to take aneurine 3 mg. daily. He was seen twenty months later for recurrence of dropped beats and dyspnœa, after he had stopped taking aneurine for two months and had been digging in his garden a lot.

He was given aneurine 3 mg. t.i.d. for four months, and then 3 mg. daily from Dec. 29, 1948. On March 21, 1949, he had right lower lobar pneumonia with dry pleurisy. On April 6, 1949, he was well and ambulant, with no cardiac damage. On Jan. 6, 1950, he was still well, with blood-pressure 140/70.

Aneurine thus seems to restore the cardiac cells to normality, and may have a beneficial effect on conduction in the bundle of His.

VITAMIN B_{12} IN MEGALOBLASTIC ANÆMIAS

SIR,—In referring to the effect of vitamin B_{12} in megaloblastic anæmias without gastric atrophy, Dr. Tuck and Dr. Whittaker (April 22, p. 757) incorrectly abbreviate a report[1] of my remarks at the British Association meeting last year which was already too condensed to be accurate. These anæmias are a "mixed bag" and the response to vitamin B_{12} varies widely. It is true that megaloblastic anæmias of pregnancy and the puerperium in temperate climates did not respond,[2] but Patel and Kocher[3] report good results in a tropical variety of the syndrome.

Megaloblastic anæmias associated with intestinal disorders—even those encountered in this country—have not always failed to respond to vitamin B_{12}.[4 5] On the other hand, a state refractory to vitamin B_{12} may exist temporarily even in a patient presumed to have gastric atrophy. Such cases are rare. In one instance the anæmia became responsive to vitamin B_{12} only after small amounts of folic acid had been supplied.[4] This recalls the pigs of Heinle, Welch, and Pritchard,[6] which were so depleted of hæmopoietic factors that folic acid had to be given before liver extract would work, and vice versa.

RELIEF OF PAIN IN RHEUMATOID ARTHRITIS WITH TETRAETHYLAMMONIUM BROMIDE

SIR,—In your issue of April 1, Dr. F. Heyman and his colleagues describe their experiences with tetraethylammonium bromide. That relief of pain, and therefrom increased motility, should be given by this remedy is in complete harmony with the theory of pain production which I give in the second edition of my *Treatment of Some Chronic and Incurable Diseases* (1947). This is an extension of Mackenzie's theory to embrace the autonomous system, especially its vasomotor system. The whole is too long to embody in a letter, but an important paragraph is:

> "Now it was pointed out above that pain stimuli pass also by the autonomous nerves which are present in all tissues; it is the stimuli which are conducted by them which I think important as pain producing, for they induce vaso-constriction in the myotome concerned and so tend to produce this local ischæmia of the nerve endings which, as a result, register pain" (p. 260).

My thesis is, in brief, that local trauma induces an adrenergic overplay causing ischæmia in the affected myotome; thus also giving a reason for so-called referred pain. In addition the theory gives help in the understanding of relief of arthritic pain from ascorbic acid with deoxycortone, both of which would tend to correct overplay of the adrenal medulla by assisting the cortex—i.e., Hallion's "law": the administration of a gland extract causes increased action of that gland. In two cases of Addison's disease I found that massive ascorbic acid resulted in considerable lightening of pigmented skin and mucosa.

But there is one aspect of pharmacologic knowledge which is lacking at present as regards drug action. Why should a vasodilator, for example, act maximally on the pathologically constricted blood-vessels and not on al the blood-vessels? It would almost seem that drug action may operate in direct proportion to the intensity of the nervous impulses in activity.

Bristol. A. T. TODD.

THE REGISTRAR'S FUTURE

SIR,—I was particularly interested in Mr. Mitchiner's letter last week because the association of which I have the honour to be president is most concerned with this problem at the moment.

Registrars at non-teaching hospitals, though they gain a very large experience, find that when they apply for promotion to a consultant post, even in a non-teaching hospital, they are severely handicapped as the appointment committee is very largely composed of teachers, and if a registrar from a non-teaching hospital is competing against a registrar from a teaching hospital the latter, though possibly junior and with less practical experience, will probably get the job. Young men tend, therefore, to hang about the teaching hospitals fearful to venture into the periphery lest they quit irrevocably the ladder of promotion.

If this state continues the non-teaching hospitals, in spite of the practical experience they afford, will be unable to get satisfactory applicants for registrar posts, and a general decline in efficiency will result. Furthermore, the disadvantages of inbreeding within the teaching hospitals will be accentuated. I am sure it would be a great advantage to both teaching and non-teaching hospitals if consultants on both had the widest experience, and I feel that registrars should be encouraged to widen their experience by a term of service in a regional hospital, not because of pious exhortations to clear the congestion at the centre and by so doing diminish the field of applicants for promotion, but because such experience would be regarded as an asset, if not an essential qualification, when appointments of consultant rank were made in either teaching or non-teaching hospitals.

H. J. MCCURRICH
President, Regional Hospitals' Consultants and Specialists Association (Non-Undergraduate Teaching Hospitals).
45, Lincoln's Inn
Fields, W.C.2.

SIR,—Mr. Mitchiner's letter last week is of importance not only to registrars but also to all those who are concerned with the staffing of medical posts abroad. In the past such posts have very largely been filled by men who chose to spend twenty or thirty years of their lives in Africa, India, or the East. Similar posts are available now. Most posts advertised for short terms of service are unattactive owing to the uncertainty as to what will happen when the contract ends.

But there are, I believe, some posts—and the number of these may increase—to which those who have special experience and higher qualifications would be welcomed for periods of from four to six years. I am thinking particularly of general physicians, general surgeons, orthopædic and ophthalmic surgeons, gynæcologists, anæsthetists, psychiatrists, and those who practise physical medicine. Here again the main problem is that of reabsorption in this country when their period of foreign service is over. I can only suggest that some or all of the regional boards, with the concurrence of the Ministry of Health, might be willing in the interests of British medicine to increase their specialist or consultant establishments to include some supernumerary posts, so as to allow of secondment of a limited number at a time for work abroad. This would involve financial arrangements being worked out between the two employers. But it is no new thing to second men in established posts in Government service in this country to Government

posts abroad for limited periods without loss of status and pension rights, &c., on return. It might even be possible for one particular regional board in this country to develop a special liaison with one Dominion, Colonial, or Protectorate government on these lines.

The matter is urgent and demands very early consideration, though some delay seems inevitable until the various regional boards have at last been able to declare their consultant establishments.

Public Health

Epidemics in Schools

IN 1929 the Medical Research Council appointed a committee to investigate epidemic and other illness in schools. An interim report, based on detailed morbidity statistics from a number of boys' and girls' public schools and some Naval schools, was published in 1938.[1] An analysis of the data collected during the years 1935–39 now appears as a sequel.[2] Taken together, the two reports present a detailed picture of the illnesses that affected a sample school-age population during ten years.

Some of the most interesting findings relate to the large, ill-defined, and ubiquitous group of nasopharyngeal infections. Influenza is shown to have been an epidemic disease essentially belonging to the spring term, with a universally high attack-rate in 1937: this presumably reflected a generalised epidemic since Influenza Deaths in Great Towns showed a corresponding peak. There was no evidence that infection in this year conferred any immunity towards a second epidemic two years later. Other nasopharyngeal infections (sore throat, colds, chills, coughs) were the commonest causes of sickness, and these also showed highest attack-rates during the spring term. An interesting finding here was an attack-rate on girls' schools 150–300% higher than on boys' schools: the difference was especially evident in the case of colds and did not apply to sore throat. A high correlation was shown between the attack-rates of otitis media and sore throat in both boys' and girls' schools, and between otitis media and all nasopharyngeal infections in boys' schools. In girls' schools, however, there was a negative correlation between otitis media and all nasopharyngeal infections. The incidence of sinusitis showed a precisely similar behaviour. The report suggests that these apparently anomalous findings were connected with the much higher attack-rate, already mentioned, in girls' schools of nasopharyngeal infections; the coughs and colds were perhaps treated more seriously and in consequence the complications were fewer. Non-muscular rheumatism, though often associated in the individual case with a history of sore throat, did not show a correlation with attack-rates of sore throat; but scarlet fever and non-muscular rheumatism showed a high correlation. In this connection it seems a great pity that no test for correlation between sore throat and scarlet fever was made, since the occurrence of cases of scarlet fever as incidents in a wider epidemic of infectious sore throat must be a common experience.

Turning to the exanthemata and mumps and whooping-cough, it is shown that these occurred more often in the spring and summer terms than in the winter term, with the exception of chickenpox. The sex-incidences did not differ significantly, except in the case of whooping-cough which occurred more often in girls. Measles showed a significantly larger number of single-case outbreaks in girls' than in boys' schools; the report suggests that this again is connected with the higher incidence of nasopharyngeal infection, already noted, in girls' schools: if the minor catarrhs are put to bed earlier, cases of measles will be more often isolated in the early infectious stages. The association between herpes zoster and chickenpox was again observed.

Another finding worth mentioning was the much lower incidence of tinea cruris in those schools that practised isolation of this complaint. The sceptical, however, may ask whether the latter finding is not due to a high rate of concealment, since isolation for what is usually a trivial complaint will not appeal to the schoolboy.

On the whole it must be admitted that this report does not throw much new light on the general problems of epidemiology. Perhaps one reason for this is that the residential school is a "semi-isolated community" only in a very limited sense, since its inmates form part of the general community for a third of the year; and no epidemic runs a natural course, because of the disruption of the community at the end of term. On the other hand the report (with its predecessor) fulfils two important purposes. In the first place it provides statistical proof of a number of phenomena which, though well recognised by many workers in school medicine, have existed only as general impressions unchecked by figures. In the second place it provides a work of reference of great value for all future workers in this field.

Smallpox

Certain cases of smallpox or suspected smallpox have come to light:

1. A girl who arrived in this country by air from Switzerland on April 28 attended the outpatient department of a London teaching hospital with a generalised rash which raised a suspicion of smallpox. All precautions were taken accordingly, pending laboratory investigations. These ultimately proved the case to be one of generalised vaccinia.

2. On May 5 a man was taken off an aeroplane due to depart from Northolt for Renfrew, with signs and symptoms of an acute illness accompanied by a rash. The airport medical officer considered there was the possibility of the case being one of smallpox, and the man, after being seen by a smallpox consultant, was removed to isolation. This man had earlier the same day landed at London Airport from Calcutta, which he had left on May 3. All the necessary administrative action was taken, including notification of the circumstances of the case to countries to which contacts were proceeding. Laboratory examinations do not confirm the original suspicion, and the case is not now regarded as one of smallpox.

3. On May 4 and 5 two patients from Halifax and one from Sowerby Bridge, adjacent to Halifax, were taken into isolation as cases of smallpox. The normal preventive measures were at once put in hand by the local authorities concerned.

could still recognise the good companionship and courage of their old friend."

A big man—he was over six foot and broad in proportion—Corner had done a good deal of mountaineering in his youth. Later he had turned to his other interests of mycology and architecture. He married in 1903 Miss Henrietta Henderson, who survives him with a son and two daughters.

HUBERT JOHN STARLING

M.D. LOND.

Dr. H. J. Starling, consulting surgeon to the Norfolk and Norwich Hospital, died on April 10 at the age of 76.

He was born in Bombay, where his father, the late Matthew H. Starling, was clerk of the Crown; and his elder brother was E. H. Starling, the physiologist. He returned to England for his education, and from St. Paul's School he went to Guy's Hospital where he graduated M.B. in 1897, taking his M.D. two years later. He held house-appointments at Guy's and served as a civil surgeon with the South African Field Force before settling in general practice in Norwich in 1902. For some years he was also medical officer to the Norwich prison.

Early in the 1914–18 war he was rejected for service on medical grounds, but in 1917 he was given a commission in the R.A.M.C. and attached to Colchester Military Hospital, where he worked under Sir Thomas Lewis. Here he undertook investigations into the problems of disordered action of the heart (" D.A.H.") and this interest led him to specialise in cardiology. For a time he studied under Sir James Mackenzie, and when he returned to Norwich after the war he gave up general practice to become a consultant. He was appointed to the staff of the Norfolk and Norwich Hospital and consulting cardiologist to the eastern division of the Ministry of Pensions. He was also on the staff of the Norfolk Mental Hospital and of St. Andrew's Hospital, Thorpe.

Starling's enthusiasm for cardiology continued and he became a member of the cardiac branch of the Association of Physicians and he was a founder member of the Cardiac Club. He also wrote many interesting and erudite papers on angina pectoris and coronary occlusion, and the Starling-Ford stethoscope is named after him. His practice was not however limited to this specialty and he had a wide practice in consulting medicine in East Anglia. Soon after he retired from his hospital appointment under the age-limit, in 1939, he was invited to become chairman of the Norwich medical board of the Ministry of Labour and National Service and he held this office till last year.

A colleague writes: "Starling was notable for his energy and keen interest in his profession and for his chin, indicative of thrust and determination. He had a somewhat acid wit, but he was kindly and considerate and companionable. In his latter days he was troubled by a fibrositis which curbed his energies, but his keenness and interest in his profession persisted."

Dr. Starling was prominent in Norwich musical circles and he served on the committees of the Norfolk and Norwich triennial festival and of the Norwich Philharmonic Society. He married a daughter of the late Dr. Thomas Fairbank, of Windsor, and she survives him with two sons, one of whom is Dr. Evelyn Starling, of Eccleshall, Staffs.

ERNEST MARTIN

M.B. DURH.

Dr. Martin, who died at his home in Didsbury, Manchester, on April 17, joined the staff of the Ministry of Health in 1925. After graduating M.B. from Durham University in 1906 he built up an extensive general practice in Oldham, where he was secretary to the Oldham Medical Society. On joining the Ministry he was posted first to Newcastle and then to Nottingham. He then became deputy divisional medical officer in the North-Eastern division at Leeds, and in 1936 he was appointed divisional medical officer in the North-West division. During the 1939–45 war, he was mainly concerned with the supervision of National Service medical boards in the North-West Region of the Ministry of Labour and National Service. In 1945 he successfully undertook the difficult task of setting up the regional medical service. After his retirement in 1946 he still continued to work on medical boards for the Ministry of Pensions.

B. B. writes: " Those of us who worked with Ernest Martin during the war years, and were in close touch with the man and his methods, will feel a real sense of loss at his passing. The medical boards gave full play to his remarkable organising ability, and he was immensely proud of the work they were doing, and took an intense personal interest in his doctors. Most of us were in general practice, and already overworked; boards were many and the strain was great; but he cheerily moved among us, and his advice and help were there for the asking. He was keen on efficiency, he expected a great deal and he got it. I went North with him on several occasions when he visited other boards, and I could not help being impressed by the warmth and affection with which he was always greeted, not only by his colleagues but by the whole staff. I had known him slightly for 30 years, but an ever deepening friendship began when I began to work with him. His last illness was borne with fortitude, and greatly eased by the devotion of his wife and two daughters."

Diary of the Week

MAY 14 TO 20

Monday, 15th

Royal College of Physicians, Pall Mall East, S.W.1
5 P.M. Dr. Geoffrey Evans: Arthritis of the Spine.
West London Medico-Chirurgical Society
8.30 P.M. (1, Wimpole Street, W.1.) Admiral Lord Mountevans: Antarctic Exploration. (Cavendish lecture.)

Tuesday, 16th

Royal College of Physicians
5 P.M. Sir Charles Symonds: Migraine.
University of London
5.15 P.M. (Bedford College, N.W.1.) Prof. Winifred Cullis: Women in Medicine. (Fawcett lecture.)
5.30 P.M. (University College, W.C.1.) Prof. H. Piéron (Paris): Les problèmes fondamentaux de la psychophysique dans la science actuelle. (First of two lectures in French.)
Institute of Dermatology, 5, Lisle Street, W.C.2
5 P.M. Dr. D. I. Williams: Sex Hormones in Dermatology
Edinburgh Post-Graduate Board for Medicine
5 P.M. (University New Buildings, Teviot Place.) Dr. William Evans: Common Faults in the Diagnosis of Heart-disease.

Wednesday, 17th

University of London
5.15 P.M. (University College.) Prof. F. Bremer (Brussels): Physiology of the Central Nervous System. (First of three lectures.)
North-East London Clinical Society
8 P.M. (Prince of Wales's General Hospital, Tottenham, N.15.) Dr. F. E. Camps: Clinical Application of Forensic Medicine.

Thursday, 18th

Royal Society of Tropical Medicine and Hygiene, 26, Portland Place, W.1
7.30 P.M. Prof. R. M. Gordon: Problem of Loiasis in West Africa.
Institute of Ophthalmology: Judd Street, W.C.1
5.30 P.M. Dr. D. Slome: Referred Pain.
St. George's Hospital Medical School, S.W.1
4.30 P.M. Dr. Partridge: Psychiatry demonstration.
British Medical Students Association
5.30 P.M. (Royal Free Hospital School of Medicine, W.C.1.) Dr. J. Thwaites: The Why and Wherefore of Medical Ethics.
Honyman Gillespie Lecture
5 P.M. (University New Buildings, Teviot Place, Edinburgh.) Dr. J. J. R. Duthie: Clinical Trials of Adrenocorticotrophic Hormone.
University of Dublin
4.30 P.M. (Trinity College.) Prof. L. J. Witts: The Life of the Red blood-cell. (Frederick Price lecture.)

Friday, 19th

Obituary

RONALD GREY GORDON

M.D., D.SC. EDIN., F.R.C.P.E.

Dr. R. G. Gordon was a man of wide medical experience. His first specialty was neurology, from which had grown his interest in hydrology and later in psychiatry and child guidance. This manysidedness was reflected in his appointments. He was physician to the Bath and Wessex Orthopædic Hospital, consulting physician to the Royal National Hospital for Rheumatic Diseases, and neurologist to the Stoke Colony for Mental Defectives, and he retired last year from the staff of the Royal United Hospital, on reaching the age limit, only to become geriatrician to the Bath clinical area.

Born in 1889, the son of Mr. Alexander Gordon of Broughty Ferry, he was educated at Charterhouse and Edinburgh University where he graduated M.B. with second-class honours in 1911, taking his M.D. two years later. After holding house-appointments at Edinburgh Royal Infirmary and Paddington Green Children's Hospital he settled in practice in Bath in 1913. But almost immediately he had to leave for four years' service in the R.A.M.C. On his return to Bath in 1919 he was appointed neurologist to the Ministry of Pensions south-western area, and the following year he joined the staff of the Royal Mineral Water Hospital. Appointments to his other hospitals quickly followed, and he was soon engaged in a thriving consultant practice.

When the British Medical Association meeting was held at Bath in 1925 Gordon, owing to the illness of others, had more or less to run the occasion at short notice. His ability and talent for organisation were quickly recognised and he was welcomed to the council of the association. In 1934 he succeeded Sir Robert Bolam as chairman of the journal committee of the association which he guided with skill and wisdom during a period of development and reconstruction. He was also a valued member of many other committees of the association, notably those on medical education, mental deficiency, lunacy law, the care of the elderly and infirm, and research into the cause and treatment of arthritis. He was also one of those responsible for the *Charter of Health*, and still more recently he had served on Sir Henry Cohen's committee on general practice and the training of the general practitioner. Membership of these committees made full use both of his extraordinary kindness and knowledge of human nature and of the quietly balanced judgment that he gave to people and things. It also entailed an extraordinary amount of work, and he would never have been able to accomplish all he did, with repeated journeys between Bath and London, but for his power of concentration. A colleague recalls him absorbedly writing a report oblivious of the children who played happily around him.

To this period also belonged his books on *Personality* (1926), and the *Neurotic Personality* (1927), while with F. G. Thomson he wrote *Physiological Principles of Hydrology* (1926), with R. J. A. Berry *The Mental Defective* (1931), with Maud Forrester-Brown *Paralysis in Children* (1933), and with Noel Harris and J. R. Rees an *Introduction to Psychological Medicine* (1936). In 1937 he delivered the Morison lectures to the Royal College of Physicians of Edinburgh, who had elected him to their fellowship in 1926. *The Uses and Limitations of Psychotherapy* and *The Philosophy of a Scientist* were more recent monographs in which he ably summarised his attitude to life and medicine.

In 1938 Gordon formed the 4th Southern General Hospital (T.A.), and when it was disbanded in 1942 he was appointed to the command of a general hospital in West Africa. Of his time there D. R. A. writes: "Gordon was one of those who can adapt themselves to a change of environment and make the most of the opportunities that present to an inquiring mind. His interests were chiefly centred round the medical work of the hospital, and by arranging clinical meetings and ward-rounds he was able to keep a lively atmosphere in spite of adverse conditions of climate. But his interests extended into the colony as a whole and he soon arranged for clinics in the larger villages of the colony. This added tremendously to the work of the hospital, and it is the best testimony to his enthusiasm to say that the extra work was undertaken with great willingness by the officers under his charge. His spare time was spent writing articles on subjects which ranged from Shakespeare's plays to psychological medicine. He also found time to cultivate a garden in the wilderness, the like of which has probably never been seen before or since; indeed everything he undertook was carried through with the utmost zest and enthusiasm. He was a man of infinite tact and great ability." In 1944 he was invalided home with amœbic dysentery and since then his health had not been good. He died on April 26 as he would have wished while still at work.

G. D. K. adds: "In a happy community of medical men there is usually one leader or father physician to whom all turn when any difficult decision is necessary. Such was the position of R. G. Gordon in Bath after we lost F. G. Thomson during the war. But perhaps he will best be remembered for his abilities in organising and his work in connection with the B.M.A., of which he was for many years a member of council. As a chairman of any committee he was difficult to revile, and he had the rare knack of knowing when to be patient, when to intervene, and what to say in summing up any difficult discussion. As a man he was admired and respected by all, and there could be no more pleasant colleague with whom to work."

Dr. Gordon married in 1913 Agnes Theodora Henderson, and they had two sons, both of whom are doctors.

EDRED MOSS CORNER

M.CHIR. CAMB., B.SC. LOND., F.R.C.S.

Mr. E. M. Corner, consulting surgeon to St. Thomas's Hospital and late surgeon to the Hospital for Sick Children, Great Ormond Street, died on May 2, after many years of ill health which had led to his premature retirement.

Born in 1873, the son of Francis Mead Corner, J.P., he was educated at Epsom College, where he was head prefect. A scholar and prizeman of Sidney Sussex College, Cambridge, he obtained a first-class in the natural sciences tripos in 1894, took his B.SC. Lond. the same year, and went on to St. Thomas's Hospital to complete his medical studies. As a student he had a distinguished career and he is believed to be the only candidate to be placed first in every subject of the Cambridge M.B. examination. He qualified in 1898 and obtained the F.R.C.S. in the following year.

After holding house-appointments at St. Thomas's Hospital and at Leeds he was appointed to the staff of St. Thomas's in 1900 and settled in consultant practice in Harley Street. In 1904 he was Erasmus Wilson lecturer at the Royal College of Surgeons, and in 1906 he proceeded to the M.CHIR. Camb.

During the 1914–18 war he served as a temporary major in the R.A.M.C. and he was also a consulting surgeon to Queen Mary's Hospital at Roehampton. In 1919 he delivered the Arris and Gale lectures at the Royal College of Surgeons and in the same year he gave the Harveian lecture to the Harveian Society, of which he was vice-president. He was also a vice-president of the Medical Society of London and of the Board of Advanced Studies of London University. He was for some time a visitor for King Edward's Hospital Fund. His first scientific paper was published in 1895 and he was a prolific and lucid writer. Besides many papers in surgical journals he published a number of books dealing with aspects of abdominal surgery, diseases of the male generative organs, and appendicitis.

A colleague writes: "Before he fell a victim to a familial degenerative nervous disease Edred Corner had shown every promise of a brilliant surgical career. As a student his ability was conspicuous, and later as a popular demonstrator and lecturer at the medical school at St. Thomas's his gifts of original observation and lucidity were well shown. The incipient nervous failure declared itself while he was still an assistant surgeon at St. Thomas's, and although slow and insidious it led to his resignation while he was still on the assistant staff. He showed great fortitude, and those who saw him latterly up to Dec. 14, 1949: but there was a production tax levied not merely on the cost of the books but on the postage, besides a charge on the parcel, and in some cases a transaction tax as well. Moreover when the bookseller has sold the books he has to pay a turnover tax and a local tax; and in December the French government re-imposed an import duty on all leather-bound books. Iceland, which prided itself on not taxing books, now levies a duty; Italy, Norway, and Switzerland all tax them; the Philippines let in U.S. publications free of charge but tax all others. Before the war hardly any country taxed books except the United States, which confined its taxes to books in English—thus in effect discriminating against books from the British Commonwealth; and this custom continues.

Sir Stanley points out how adversely the taxation of books affects students: "British medical and technical works have in large measure displaced German textbooks, but in some parts of the world where they are most needed the flow is reduced to a mere trickle. A doctor in Spain or an engineer in Japan may thus be kept waiting indefinitely for information readily available from British books." The remedy, he implies, must lie with an informed public opinion: "... no government finds it easy to defend the taxation or obstruction of knowledge when once it is publicly challenged. ..." Since the war more English books have been translated into other languages than ever before, largely owing to the work of the British Council in spreading knowledge of our way of life. If we believe that we have something useful to tell other nations, not merely about technical advances but also about living together in a community—and seeing how closely packed we are we manage with astonishingly little friction—then we can fully support Sir Stanley in this very reasonable protest.

University of Oxford

On April 27, the following degrees were conferred:

D.M.—A. H. James, *M. H. Hughes, *A. J. Wilmot.
B.M.—*R .C. Farrow.

* In absentia.

University of London

Mr. J. B. Hunter has been reappointed to the senate by the faculty of medicine, and Dr. E. R. Boland has been appointed in place of Sir Archibald Gray.

Sir Harold Boldero has been reappointed by the general medical schools.

The following have been recognised as teachers of the university in the faculty of medicine:

W. E. Gibb, medicine, St. Bart's; W. W. Brigden, medicine, London Hospital; E. J. Moynahan, dermatology, F. N. Glover, surgery, and A. R. F. Thompson, dental surgery, all at Guy's Hospital; M. D. Nosworthy, anæsthetics, J. Bishop Harman, medicine, Herbert Spencer, pathology, R. J. V. Battle, surgery, R. J. Furlong, orthopædics, and J. B. Kinmonth, surgery, all at St. Thomas's; F. J. G. Jefferiss, venereal diseases, St. Mary's; E. W. Hart, children's diseases, P. H. Newman, orthopædics, Middlesex; E. F. King, ophthalmology, Westminster; F. F. Cartwright, anæsthetics, King's College Hospital.

At recent examinations for the D.P.M., the following were successful:

C. F. Allfrey, A. S. Clenaghan, J. P. Crawford, Kalika-Charan Dubé, K. C. S. Edwards, H. V. W. Elwell, E. J. Harrison, Marie S. Paterson, B. H. Smith, A. D. Weatherhead, R. H. Wheeler, Lionel Wolman.

Royal College of Obstetricians and Gynæcologists

At recent examinations for the diploma in obstetrics, the following were successful:

G. W. E. Aitken, D. F. Alexander, C. L. S. Archer, Joseph Armstrong, Ahmed Abdel-Fattah Atallah, Dorothy J. Ball, D. C. Barker, Mary E. Barton, Margaret R. Bate, B. F. M. Bond, D. G. Bonham, D. C. Bracken, Malcolm Brown, T. W. Brown, Helen L. Burns, J. D. Bury, R. G. C. G. Carlson, Roma N. Chamberlain, O. W. W. Clarke, Isobel J. Cochrane, K. W. Cochrane, Maureen D. Connolly, V. H. Cooper, Margaret L. Cox, Denis Craddock, D. A. Davey, E. J. L. Davies, Joan M. S. Dawes, Sheila M. Dineen, N. A. Duncan, Evelyn S. Elliott, M. W. Elliott, B. F. Elton, M. W. Fordham, M. T. Gallagher, R. M. Gaunt, Edwina E. Green, P. B. Guastalla, Helen E. E. Gunn, Wladyslaw Guzdziol, T. S. Hall, G. A. Hanks, Joan Harper, I. R. Henderson, Margaret I. Hendric, Valentine M. Husband, G. J. G. Irvine, Kilpatrick Jack, P. D. C. Jackson, Beryl M. Joles, A. E. Kingston, J. H. Kuhn, Edward Lacy, Jean Learoyd, G. A. Lewis, Margaret S. V. Lewis, J. D. Llwelyn-Jones, Derrick Lonsdale, Eileen V. A. McGill, Christine R. Macgregor, D. A. Macleod, F. R. L. Makin, Joan Marshall, D. M. Maxwell, D. T. Methuen H. J. Messawer, Max Miller, G. W. Morrison, Margaret E. Murison, C. J. Murphy, Jean Murray-Jones, T. S. Nicol, Catherine Nolan, E. P. D. O'Neill, P. F. O'Neill, J. T. Paton, Margaret M. Platts, Harry Rees, W. J. St. E.-G. Rhys, R. P. Robertson, M. G. Rolfe, G. A. H. Sandilands, D. G. Scott, J. E. Senanayake, S. F. Shilliday, J. C. Smart, Cecily F. Statham, Sara I. Stinson, J. R. Sudbury, Audrey Sutherland, Tharmapuram Krishnasami Sundaram, J. J. Troy, Jehangir Sohrab Vazifdar, Helen B. Walker, F. E. Welch, Elizabeth J. Welford, Audrey M. Wells, Sheila M. Wheeler, David Wilkes, I. U. Young.

Royal College of Physicians of Edinburgh

At a meeting of the college held on May 2, with Sir David Henderson, the president, in the chair, Dr. Kenneth Cameron was elected to the fellowship. The following were elected to the membership:

G. M. Fyfe, Nathan Smith, Samuel Wayburne, K. L. G. Nobbs, R. C. Jackson, Marion B. Bethune, M. B. Feldman. S. B. Griffiths, D. H. Dracup, R. J. Fassina, G. W. Csonka, Nathan Sher, Velva Schrire, A. K. Sen, Lionel Stein, H. M. G. Shanly, J. N. C. Cooke, D. J. Ellison, R. L. Lyon, D. H. Abbott, V. V. Kalbian, P. O. Crossfield.

The Cullen prize "for the greatest benefit done to practical medicine during the four preceding years" was awarded to Prof. John McMichael, director of the department of medicine, Postgraduate Medical School of London.

Royal Faculty of Physicians and Surgeons of Glasgow

At a meeting of the faculty on May 1, with Dr. W. R. Snodgrass, the president, in the chair, C. J. Patel and D. K. Rao were admitted fellows of faculty *qua* surgeon.

London Nursing Exhibition

In connection with the conference for nurses and midwives which the *Nursing Mirror* is organising, an exhibition of nursing will be held at Seymour Hall, Seymour Place, W.1, from Oct. 23 to 27.

London County Medical Society

The next clinical meeting of the society will be held at Highwood Hospital, Brentwood, Essex, on Thursday, June 1, at 3 P.M. Further information may be had from the hon. secretary, Mr. J. Gabe, F.R.C.S., St. Alfege's Hospital, S.E.10.

Guild of Hospital Librarians

The annual general meeting of the guild will be held at Chaucer House, Mallet Place, London, W.C.1, on Wednesday, May 17, at 6 P.M., when the speaker will be Mr. Douglas Woodruff, editor of the *Tablet*.

Sir Wilson Jameson

A complimentary dinner was given on May 3 by some of the senior Aberdeen medical graduates in London to Sir Wilson Jameson on his retirement from the Ministry of Health. Those present included Vice-Admiral C. E. Greeson, medical director-general of the Navy, and Lieut.-General Sir Neil Cantlie, director-general of Army Medical Services, and it was noted that three of the premier administrative posts in the medical services have been filled simultaneously by Aberdeen graduates. After the toast of the evening had been proposed by Prof. Andrew Topping, supported by Dr. J. Watt and Dr. Adam Gray as old classmates, and by Dr. D. D. Reid as the youngest graduate present, Prof. Robert Cruickshank presented Sir Wilson with a small memento of affection and esteem. In his reply, Sir Wilson recalled his student days in Aberdeen and spoke of Ministers and administration. The administrator, he said, must be a good listener.

On May 11, at the Ministry of Health, Sir William Douglas and Sir John Charles made a presentation to Sir Wilson Jameson on behalf of the lay and medical staff.

King Edward's Hospital Fund for London announces that Sir Wilson is joining its staff, on a part-time basis. from June 1.

Fertility Conference

A conference on fertility, which will also be the inaugural meeting of a new Society for the Study of Comparative Fertility, will be held in the house of the Zoological Society of London, Regent's Park, London, N.W.1, on Friday and Saturday, June 16 and 17. On the first day Mr. Kenneth Walker will speak on the diagnosis and treatment of male infertility; Dr. R. G. Harrison and Dr. A. G. Oettlé on pathological changes in the rat testis following ischæmia; Mr. A. S. Parkes, F.R.S., on storage of mammalian spermatozoa at low temperatures; Dr. C. A. Joël on comparative studies on semen ejaculate and testis biopsies; and Mr. C. Polge on artificial insemination in the fowl. On the following day Dr. Samuel L. Siegler will give an address on aspects of infertility and show a film on *Sterility: Its Causes, Investigations and Treatment*. Mr. I. W. Rowlands, PH.D., will speak on the breeding of dogs, and Dr. Margaret Hadley Jackson on the significance of round-cell infiltration as seen in endometrial biopsy sections; Dr. Claude Béclère will show a film on *Hysterosalpingography in the Diagnosis and Treatment of Sterility*; Mr. A. Walton, PH.D., will speak on activity of spermatozoa in vitro; and Dr. Bethel Solomons will sum up with some conclusions about infertility. Further particulars may be had from Dr. G. I. M. Swyer, Obstetric Hospital, University College Hospital, Huntley Street, London, W.C.1.

Notes and News

INTERNATIONAL TRAINING CENTRE FOR ANÆSTHETISTS

AN international centre for training in techniques of anæsthesia was opened on May 3 at the Rigshospital, Copenhagen. This centre, operated jointly by the faculty of medicine of the University of Copenhagen and by the World Health Organisation, will provide a one-year course for Scandinavian and other European postgraduates. Twenty-one doctors, supported by W.H.O. fellowships, have arrived at the centre from Iceland, Norway, Sweden, Finland, Austria, Yugoslavia, and Denmark. The instructors include Dr. Stuart G. Cullen (U.S.A.), Dr. Ralph Waters (U.S.A.), and Dr. Phyllis Edwards. In many Scandinavian centres the responsibility for the direction of an anæsthetic still rests with the surgeon, and there is a general desire to establish an anæsthetic specialty. An additional 50 anæsthetists are said to be needed in Denmark.

TEACHING OF PUBLIC HEALTH

" MANY promising public health students are being diverted from a chosen career as medical officer of health, and in time to come, the unhappy circumstances of today may well have repercussions on the efficiency of our public health services." This conclusion is reached by Prof. J. M. Mackintosh in the report for 1948–49 of the London School of Hygiene and Tropical Medicine. Of 46 students who were awarded the diploma in public health during the year, 22 were British students without ready-made commitments. Yet six months after the diploma examinations, only 7—all men—had taken appointments in local government. Of the remainder, 6 had taken posts in industry, 4 in academic and research work, and 5 in general practice and other clinical posts. " What it comes to is that, though the School has 90 diploma graduates to its credit for the last two years, it has supplied only 15 recruits to our own public health service in this period."

For their elective studies in 1948–49 diploma students were offered the choice of special courses in industrial hygiene, tropical hygiene, or hospital administration. The purpose of the course in industrial hygiene, Professor Mackintosh insists, is not to provide training for consultants in industrial medicine, but to offer opportunities for the making of good general practitioners in industrial health. " We believe, like our American colleagues, that industrial health is an integral part of public health." As to tropical hygiene: " In the past there has been a recognised combination of clinical work in the tropical service with the practice of hygiene, so far as the latter could be fitted in to the clamant needs of caring for the sick. The union has been lopsided, and in consequence our knowledge of the factors affecting the public health is singularly deficient."

TUBERCULOUS PATIENTS' WASHING

WHILE a tuberculous patient is in hospital his wife or other relative is entrusted with the job of taking away his soiled personal linen and getting it washed. The ways in which she may undertake this task were discussed in our columns last year.[1] Brompton Hospital gives patients and relatives a printed set of instructions which go far to ensure that infected clothing taken home will not be a source of danger to other members of the household. They are as follows:

RECOMMENDATIONS TO TUBERCULOUS PATIENTS FOR DEALING WITH PERSONAL CLOTHING

1. All such articles must be washed separately from those belonging to others.
2. No cooking utensil should be used for washing.
3. Handkerchiefs should be placed in a cotton bag in boiling water for twenty minutes.
4. Other linen articles should be boiled for not less than ten minutes.
5. Woollen and other shrinkable articles should be aired, preferably out of doors, for twenty-four hours and then washed in the ordinary way.
6. Suits and dresses should be aired for forty-eight hours, preferably out of doors, and then sent to the cleaners.

The phrase " preferably out of doors " perhaps allows for some careless practice, for airing indoors may mean hanging the garments on to one of those overhead airing-racks, generally slung above the kitchen table; and in any case airing of infected clothing inside a crowded or overcrowded home should be discouraged. Most people can find a place for outdoor airing, if they are obliged to; and perhaps the word " preferably " should be omitted. Nevertheless these directions are clear, easy to follow, and thoroughly sensible; and similar instructions might well be handed to visiting relatives at other hospitals.

A NEW JOURNAL ON FERTILITY

Fertility and Sterility,[1] the official journal of the American Society for the Study of Sterility, replaces *Human Fertility*, another American publication, which—as the *Journal of Contraception*—started life in 1935, sponsored by the Margaret Sanger Clinical Research Bureau, and under the editorship of Dr. Abraham Stone. Those who witnessed the birth of the journal and its development will be sad to see it go; but in this first number, the new publication, edited by Pendleton Tompkins, promises to be a worthy successor. In the original journals the trend was gradually away from contraception and its practical application, and towards the investigation and treatment of infertility; hence the change of name in 1940. Now the emphasis has swung still further: the new journal will be entirely concerned with fertility and with infertility and its causes both in man and animal.

Among eight papers of varying merit in this issue, some deserve special mention. The article on dating the endometrial biopsy, by Dr. R. W. Noyes, Dr. A. T. Hertig, and Dr. J. Rock, based on their own series of 8000 biopsies and illustrated by excellent photomicrographs, is a sound piece of work and a valuable guide to other workers. In a short paper Dr. S. H. Sturgis ably discusses the mechanism and control of primate ovulation, pointing out that in each cycle a number of follicles mature but that commonly in primates only one discharges an ovum, the rest becoming atretic. The thecal cells of these atretic follicles produce œstrogen, which helps to maintain the production of luteinising hormone by the pituitary. It thus appears that these " lost " follicles have a function, but the mechanism whereby all but one or two follicles are forced into atresia has still to be elucidated. Dr. S. L. Israel and O. Schneller describe the thermogenic effect of giving progesterone to a series of 26 female castrates and 6 regularly menstruating women. Dr. J. H. Nodine and Dr. W. H. Perloff describe what they believe to be an improved technique for the quantitiatve determination of hyaluronidase in human semen. A paper on luminescent phenomena in the external female genitalia, and their correlation with sex-hormone levels, by Dr. P. A. Macdonald and Dr. M. Sydney Margolese, presents new work; the method requires somewhat elaborate apparatus and preparation; its clinical value must remain sub judice. Useful abstracts and reviews complete an interesting opening number.

TAXATION OF BOOKS

THERE is a story that Elizabethan Englishmen, visiting a foreign country, excited amusement by their passionate search for new books to take home; and we still retain enough of this traditional enthusiasm for new learning to keep the import of books reasonably free from taxation. Books from the Dominions (other than Canada) and from the Colonies and most of the sterling and soft-currency areas, Sir Stanley Unwin [2] tells us, can be freely imported under open general licence. Importation from hard-currency countries is limited, but even so we are free to import twice as much from the United States as before the war.

When it comes to selling books abroad, however, the restrictions imposed by Governments are exceedingly daunting; and he gives several examples. In Belgium books are taxed by weight. In Brazil there is a tax on all books in cloth or leather binding, plus handling charges which amount to 10% or more of the value of the whole consignment, and consular invoices costing upwards of £5 for all packets worth £9 or more; and a fine is imposed if the consular invoices are not provided. It is often cheaper, Sir Stanley remarks, to pay the fine instead of the consular charge. If a few catalogues are included, the consignment becomes liable for the import duty on foreign publicity material. The Brazilian government seems to be against reading altogether, for bookshops are classified in the same high income-tax category as brothels. Canada has an 8% sales tax on imports, from which books are not exempt, though pornographic magazines, it seems, are. Cuba has an array of taxes for everything except textbooks, and like Finland first imposes an import duty, and then adds a tax on the duty-paid value—thus taxing a tax. France had, in theory, no duty on books

2. How Governments Treat Books. London: George Allen & Unwin. 1950. Pp. 9. *6d.*

up to Dec. 14, 1949; but there was a production tax levied not merely on the cost of the books but on the postage, besides a charge on the parcel, and in some cases a transaction tax as well. Moreover when the bookseller has sold the books he has to pay a turnover tax and a local tax; and in December the French government re-imposed an import duty on all leather-bound books. Iceland, which prided itself on not taxing books, now levies a duty; Italy, Norway, and Switzerland all tax them; the Philippines let in U.S. publications free of charge but tax all others. Before the war hardly any country taxed books except the United States, which confined its taxes to books in English—thus in effect discriminating against books from the British Commonwealth; and this custom continues.

Sir Stanley points out how adversely the taxation of books affects students: "British medical and technical works have in large measure displaced German textbooks, but in some parts of the world where they are most needed the flow is reduced to a mere trickle. A doctor in Spain or an engineer in Japan may thus be kept waiting indefinitely for information readily available from British books." The remedy, he implies, must lie with an informed public opinion: ". . . no government finds it easy to defend the taxation or obstruction of knowledge when once it is publicly challenged. . . ." Since the war more English books have been translated into other languages than ever before, largely owing to the work of the British Council in spreading knowledge of our way of life. If we believe that we have something useful to tell other nations, not merely about technical advances but also about living together in a community—and seeing how closely packed we are we manage with astonishingly little friction—then we can fully support Sir Stanley in this very reasonable protest.

Morrison, Margaret E. Murison, C. J. Murphy, Jean-Murray-Jones, T. S. Nicol, Catherine Nolan, E. P. D. O'Neill, P. F. O'Neill, J. T. Paton, Margaret M. Platts, Harry Rees, W. J. St. E.-G. Rhys, R. P. Robertson, M. G. Rolfe, G. A. H. Sandilands, D. G. Scott, J. E. Senanayake, S. F. Shilliday, J. C. Smart, Cecily F. Statham, Sara I. Stinson, J. R. Sudbury, Audrey Sutherland, Tharmapuram Krishnasami Sundaram, J. J. Troy, Jehangir Sohrab Vazifdar, Helen B. Walker, F. E. Welch, Elizabeth J. Welford, Audrey M. Wells, Sheila M. Wheeler, David Wilkes, I. U. Young.

Royal College of Physicians of Edinburgh

At a meeting of the college held on May 2, with Sir David Henderson, the president, in the chair, Dr. Kenneth Cameron was elected to the fellowship. The following were elected to the membership:

G. M. Fyfe, Nathan Smith, Samuel Wayburne, K. L. G. Nobbs. R. C. Jackson, Marion B. Bethune, M. B. Feldman. S. B. Griffiths, D. H. Dracup, R. J. Fassina, G. W. Csonka, Nathan Sher, Velva Schrire, A. K. Sen, Lionel Stein, H. M. G. Shanly, J. N. C. Cooke, D. J. Ellison, R. L. Lyon, D. H. Abbott, V. V. Kalbian, P. O. Crossfield.

The Cullen prize "for the greatest benefit done to practical medicine during the four preceding years" was awarded to Prof. John McMichael, director of the department of medicine, Postgraduate Medical School of London.

Royal Faculty of Physicians and Surgeons of Glasgow

At a meeting of the faculty on May 1, with Dr. W. R. Snodgrass, the president, in the chair, C. J. Patel and D. K. Rao were admitted fellows of faculty *qua* surgeon.

London Nursing Exhibition

In connection with the conference for nurses and midwives which the *Nursing Mirror* is organising, an exhibition of nursing will be held at Seymour Hall, Seymour Place, W.1, from Oct. 23 to 27.

London County Medical Society

The next clinical meeting of the society will be held at Highwood Hospital, Brentwood, Essex, on Thursday, June 1, at 3 P.M. Further information may be had from the hon. secretary, Mr. J. Gabe, F.R.C.S., St. Alfege's Hospital, S.E.10.

Guild of Hospital Librarians

The annual general meeting of the guild will be held at Chaucer House, Mallet Place, London, W.C.1, on Wednesday, May 17, at 6 P.M., when the speaker will be Mr. Douglas Woodruff, editor of the *Tablet*.

Sir Wilson Jameson

A complimentary dinner was given on May 3 by some of the senior Aberdeen medical graduates in London to Sir Wilson Jameson on his retirement from the Ministry of Health. Those present included Vice-Admiral C. E. Greeson, medical director-general of the Navy, and Lieut.-General Sir Neil Cantlie, director-general of Army Medical Services, and it was noted that three of the premier administrative posts in the medical services have been filled simultaneously by Aberdeen graduates. After the toast of the evening had been proposed by Prof. Andrew Topping, supported by Dr. J. Watt and Dr. Adam Gray as old classmates, and by Dr. D. D. Reid as the youngest graduate present, Prof. Robert Cruickshank presented Sir Wilson with a small memento of affection and esteem. In his reply, Sir Wilson recalled his student days in Aberdeen and spoke of Ministers and administration. The administrator, he said, must be a good listener.

On May 11, at the Ministry of Health, Sir William Douglas and Sir John Charles made a presentation to Sir Wilson Jameson on behalf of the lay and medical staff.

King Edward's Hospital Fund for London announces that Sir Wilson is joining its staff, on a part-time basis, from June 1.

Fertility Conference

A conference on fertility, which will also be the inaugural meeting of a new Society for the Study of Comparative Fertility, will be held in the house of the Zoological Society of London, Regent's Park, London, N.W.1, on Friday and Saturday, June 16 and 17. On the first day Mr. Kenneth Walker will speak on the diagnosis and treatment of male infertility; Dr. R. G. Harrison and Dr. A. G. Oettlé on pathological changes in the rat testis following ischæmia; Mr. A. S. Parkes, F.R.S., on storage of mammalian spermatozoa at low temperatures; Dr. C. A. Joël on comparative studies on semen ejaculate and testis biopsies; and Mr. C. Polge on artificial insemination in the fowl. On the following day Dr. Samuel L. Siegler will give an address on aspects of infertility and show a film on *Sterility: Its Causes, Investigations and Treatment*. Mr. I. W. Rowlands, PH.D., will speak on the breeding of dogs, and Dr. Margaret Hadley Jackson on the significance of round-cell infiltration as seen in endometrial biopsy sections; Dr. Claude Béclère will show a film on *Hysterosalpingography in the Diagnosis and Treatment of Sterility*; Mr. A. Walton, PH.D., will speak on activity of spermatozoa in vitro; and Dr. Bethel Solomons will sum up with some conclusions about infertility. Further particulars may be had from Dr. G. I. M. Swyer, Obstetric Hospital, University College Hospital, Huntley Street, London, W.C.1.

International Dental Congress

The 11th International Dental Congress of the Fédération Dentaire Internationale will take place in London from July 19 to 26, 1952, under the presidency of Dr. Wilfred Fish. Further information may be had from the organising secretary, 13, Hill Street, London, W.1.

St. Thomas's Hospital Musical Society

This society will perform Faure's requiem, and anthems by Weelkes, Gibbons, and Purcell in St. Sepulchre's Church, Holborn, on Tuesday, May 23, at 8.30 P.M. The conductor will be Dr. W. Dykes Bower, and the organist Mr. J. Dykes Bower, D.MUS. No tickets are required.

Newsholme Lectures

These lectures were endowed by the late Sir Arthur Newsholme, and Sir Henry Cohen will deliver the first course at the London School of Hygiene, Keppel Street, W.C.1, on May 22, 23, and 24, at 6.15 P.M. His subject is to be the Clinical Contribution to Public Welfare. Dr. H. P. Newsholme will take the chair at the first lecture.

W.H.O. Antibiotics Programme

The W.H.O. expert committee on antibiotics, which met in Geneva last month under the chairmanship of Mr. E. B. Chain, PH.D., F.R.S., recommended that the organisation should sponsor antibiotic research programmes and grant fellowships for long-term research. Several institutes, it was proposed, should be asked to provide research and training facilities. The committee proposed, too, that type culture collections should be deposited in certain institutions; and the scientific abstracting services should be asked to publish a combined issue containing abstracts of all available reports on antibiotics. The committee expressed the opinion that W.H.O. should organise controlled investigations of new drugs.

Presentation to Prof. Carl Browning

On April 28 a bronze bust of himself was presented to Prof. Carl Browning, F.R.S., on his retirement from the chair of bacteriology in the University of Glasgow, which he has held for 30 years. In making the presentation Sir Robert Muir, F.R.S., said: "Many teachers of the present day would benefit if they knew both what bacteriology was and how much Browning thought it necessary to teach the ordinary medical student. If they cut their courses accordingly I think it would be of great importance in the medical curriculum." The bust, which was executed by Mr. Benno Schotz, R.S.A., was afterwards accepted by the university for inclusion in their fine arts collection. Prof. D. F. Cappell presented Mrs. Browning with a gift of cutlery.

Committee on Internal Administration of Hospitals

The Central Health Services Council has appointed a committee, with 17 members, "to consider and report on the existing methods of administration in individual hospitals with particular reference to (1) matters of finance, staff, and supplies; (2) the extent to which differences in the work undertaken at different hospitals call for differences in their administrative organisation; and (3) the extent to which administrative duties should be undertaken by medical and nursing staff." Alderman Bradbeer is the chairman, and the medical members are Sir Ernest Rock Carling, Dr. A. A. Cunningham, Dr. H. G. Dain, Dr. W. G. Masefield, Dr. J. R. Murray, and Dr. J. Watt. Any person or body wishing to submit evidence should give notice to the joint secretaries of the Committee, Room 28, First Floor, Ministry of Health, S.W.1.

Retirement of Dr. M. C. Hogarth

Dr. Margaret Hogarth is to retire on June 30 from her post as a senior medical officer in the public-health department of the L.C.C.

Dr. Hogarth has served with the council since 1912, except for a period between 1925 and 1929 when she held an appointment at the Ministry of Health. In 1929 she surveyed district nursing in London; and her recommendations deali
and general conditions were accepted as a
country. When appointed, in 1931, as
medical officer, she was engaged on school health work. Later, as a divisional medical officer, she was in charge of the northern
division of the council's school
became responsible for residenti
work. In 1937 she served as the
Nutrition Committee of the Lea
she took charge of the council
under the
Health Se
from the
and child-welfare services.

Appointments

Carpenter, W. H. K., M.B. Brist.: deputy medical superintendent, Stoke Park Colony, Stapleton, Bristol.

Edge, May, M.B. Glasg., D.P.H.: asst. county M.O., North-West Kent.

Gold, S. C., M.A., M.B. Camb., M.R.C.P.: asst. physician, skin department, St. George's Hospital, London, and consultant dermatologist, Hammersmith Hospital, and senior lecturer in dermatology at the *Postgraduate Medical School*.

Graf, K. A., M.D. Vienna, D.P.M.: asst. psychiatrist (S.H.M.O.), Brentwood Mental Hospital.

Griffin, B. P., M.A. Camb., M.R.C.S.: deputy medical superintendent, Hortham Colony, Almondsbury, Bristol.

Hesling, A. G., M.B. Lond., M.R.C.P., D.C.H.: consultant pædiatrician, Blackpool and Preston hospital centres.

Lee, Constance, M.B. Lpool, D.OBST.: asst. M.O., maternity and child welfare, Manchester.

*Lochhead, Helenor, M.B. Edin.: house-physician, Hospital for Sick Children, Gre on.

McCaughan, D. V., M.B. se, and throat surgeon, Antrim, Larne, and Magherafelt, Northern Ireland.

MacKeith, S. A., O.B.E., M.R.C.S., D.P.M.: consultant psychiatrist, Hellesdon Mental Hospital.

McKirdy, A. A., M.B. Glasg., M.R.C.O.G.: surgical officer (B1), gynæcological unit, Stoke Mandeville Hospital.

Montuschi, Elio, M.D. Florence, M.R.C.P.: physician, Italian *Hospital, London.*

Raffle, P. A. B., M.D. Lond., D.P.H., D.I.H.: senior asst. M.O., London Transport.

Savage, O. A., O.B.E., M.R.C.P.: consultant, rheumatism department, *West London Hospital*.

Steiner, R. E., M.B. N.U.I., D.M.R.: radiologist, department of radiodiagnosis, Hammersmith Hospital.

Turner, J. G. S., C.M.G., M.B., B.SC. Glasg., D.T.M., D.P.H.: asst. county M.O. and M.O.H. no. 4 health area, Cornwall.

Willey, C. B. I., M.B.E., M.C., M.A., B.M. Oxfd, M.R.C.P.: senior registrar in general medicine, Norfolk and Norwich Hospital.

* Amended notice.

Births, Marriages, and Deaths

BIRTHS

Dobree.—On April 29, in London, the wife of Mr. John Dobree, M.S.—a son.

Gauld.—On April 29, the wife of Dr. G. O. Gauld—a daughter.

Gill.—On April 30, at Godalming, the wife of Mr. W. G. Gill, F.R.C.S.—a son.

Glaser.—On May 4, at Cambridge, the wife of Dr. M. Glaser—a daughter.

Gurling.—On May 6, the wife of Dr. Kenneth Gurling—a son.

Harcourt.—On April 23, in London, the wife of Dr. R. G. Harcourt—a daughter.

Hutchison.—On May 1, the wife of Mr. J. B. Hutchison, F.R.C.S.—a son.

Johnson.—On May 4, the wife of Dr. Peter Johnson—a son.

Jones.—On May 3, in London, the wife of Mr. H. O. Jones, F.R.C.S.—a daughter.

Lutton.—On April 28, at Ashton-on-Mersey, the wife of Dr. R. A. Lutton—a son.

Wetherell.—On May 4, at Birkenhead, the wife of Dr. Geoffrey Wetherell—a son.

Wright.—On April 29, in London, the wife of Dr. John Wright—*a son.*

MARRIAGES

Beswick—Welch.—On April 29, at Over Whitacre, Joseph Hubert Beswick, M.B., to Sylvia Joan Welch.

Mayne—Doy.—On May 6, at Brighton, Cyril Frederick Mayne, O.B.E., F.R.C.S., to Gladys Lillian Doy.

DEATHS

3, at West Worthing, Frank Marsden Burnett, aged 80.

at Beaconsfield, Edred Moss Corner, M.A., M.B., M.CHIR. Camb., B.SC. Lond., F.R.C.S.

Edwards.—On May 4, at Bromley, Frederic William Edwards, M.R.C.S., aged 80.

Galt.—On May 4, William James Galt, M.A., B.M. Oxfd.

Gellatly.—On May 6, at Bramhall, Cheshire, David Gilbert Gellatly, L.R.C.P.E., aged 72.

Goodfellow.—On May 1, at Chesterfield, James Anderson Goodfellow, M.B. Glasg., aged 85.

Gray.—On May 1, at Driffield, Yorks, Thomas Gray, M.B. Glasg., aged 31.

Hay iverpool on May 2, Ronald John Gwynne R.C.S., aged 38.

Low Lancaster, Richard Charles Lowther, M.B. Edin.

Mackworth.—On May 3, at Dyce, Aberdeenshire, Norman Walter Mackworth, M.B. Aberd., F.R.C.S.E., lieut.-colonel, I.M.S. retd.

McLeay.—On April 30, Charles William McLeay, B.A., M.D. West. Univ. Ont., D.P.H.

Pike.—On May 6, in London, Douglas Reginald Pike, M.A., B.M. Oxfd.

Mr. Victor Bonney has been elected an honorary fellow of the Association of Surgeons.

Prof. John McMichael, under the auspices of the British Council, is making a lecture tour during May in Denmark, Sweden, Finland, and Norway at the invitation of Scandinavian medical organisations.

VALUE OF ELECTROMYOGRAPHY IN CLINICAL NEUROLOGY

FRANK SARGENT
M.D. Lond., M.R.C.P.
SENIOR REGISTRAR, WEST END HOSPITAL FOR NERVOUS DISEASES; REGISTRAR, ELECTRODIAGNOSTIC SECTION, ST. THOMAS'S HOSPITAL; NEUROLOGIST, ST. STEPHEN'S HOSPITAL, CHELSEA

THE application of electromyography is limited to the lower motor neurones and the voluntary muscles. Although still in the experimental stage this method of investigation can supply information which may be of considerable importance in the solution of certain neurological problems. As with electrocardiography in heart-disease and radiography in pulmonary disease, electromyography should be used as an aid to diagnosis only after full and careful clinical examination. Without a clear clinical picture in his mind the physician may often find machines more misleading than useful in any branch of medicine.

Beginning as an experimental method in the physiological laboratory, electromyography was applied with great success in the diagnosis and prognosis of peripheral nerve injuries during the war. It has now been developed to a point where it can be relied on for special information in a wide range of everyday neurological disorders.

A brief description of some of the phenomena encountered in electromyography is necessary, but for a full description of all the reactions and relevant theories the reader is referred to the many excellent articles that Buchtal (1949) mentions in the report of the International Neurological Congress. Technical details of apparatus and its operation are beyond the scope of this communication; they, also, can be found in the various contributions that have appeared (Tyler 1950, Richardson 1950).

Maximal contraction of normal voluntary muscle produces a low-pitched rumble in the loud-speaker, and a sustained interference pattern on the cathode-ray screen (fig. 1). This pattern may be modified and attenuated by disease or injury until discrete motor-unit potentials only are seen (fig. 2), and, finally, no spikes at all appear on the screen and the loud-speaker is silent. Normal muscle is silent at rest.

Fibrillation in denervated muscle is seen on the screen as rhythmically repetitive potentials (fig. 3) of short duration and small amplitude (1–2 millisec., 50 μV) and is demonstrated as regular staccato ticking in the loud-speaker.

Synchronisation means the simultaneous occurrence of potentials from separate electrodes in different parts of the muscle on minimal contraction; such potentials are large—i.e., about 5–10 millisec. and up to 200 μV (fig. 4). Opinions differ about the cause of synchronisation, but all workers agree that it is seen so often in association with diseases of the spinal cord—e.g., anterior poliomyelitis—that it may be taken as strong evidence of a lesion affecting the anterior-horn cells.

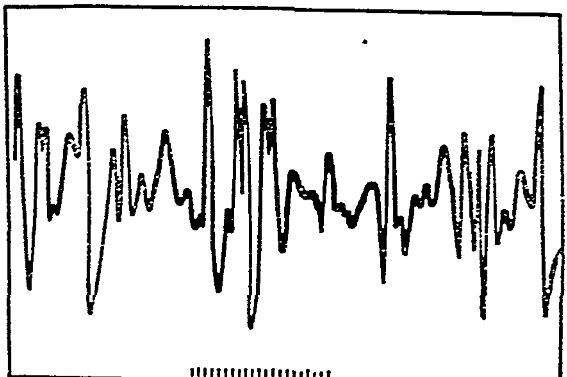

Fig. 1—Normal sustained pattern of motor-unit activity (scale: millisec.).

Other terms in common use will be explained below as they arise.

As Bauwens (1948) has pointed out, electromyographic examination should always be preceded by muscle-testing with a suitable rectangular-wave stimulator, because a combination of the two procedures gives a much more complete picture than either alone, and often indicates which muscles demand investigation. The plotting of an intensity-duration curve (fig. 5) has now taken the place of the "reaction of degeneration" test.

The cases described here all presented some point of doubt or difficulty which was considerably clarified by electromyography. For convenience of discussion the cases are grouped anatomically.

SPINAL CORD

Case 1.—A retired tailor, aged 74, complained of weakness of both arms and legs of gradual onset during the preceding eighteen months with pins-and-needles in the hands.

On examination there was gross wasting and weakness of deltoid, spinati, biceps, triceps, brachioradialis and flexors and extensors of wrist on both sides. The small muscles of the hands were not affected. Arm-jerks were normal except for a slight exaggeration of the triceps-jerks. Knee and ankle jerks were normal, the plantar reflexes were flexor, and the abdominal reflexes were present. No fasciculation was seen. Radiography of the cervical spine showed some osteo-arthritis. Total protein in the cerebrospinal fluid (C.S.F.) was 60 mg. per 100 ml.; the fluid was otherwise normal.

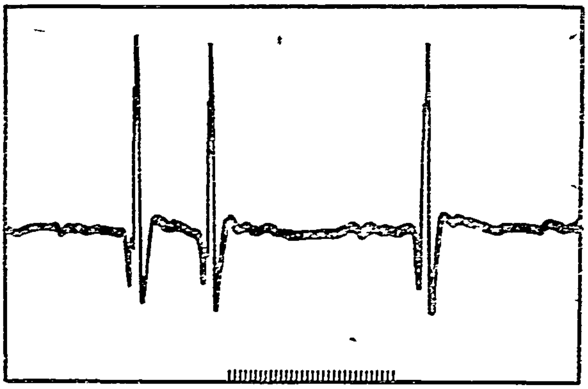

Fig. 2—Discrete motor-unit activity (scale: millisec.).

Muscle-testing revealed complete denervation (fig. 5c) of left deltoid.

Electromyography.—Needle electrodes showed decreased motor-unit activity on volition in left biceps and extensor digitorum communis, with definite synchronisation in these two muscles; and fibrillation potentials were detected in the extensor digitorum communis at rest.

Diagnosis.—These findings were considered to be compatible with a diagnosis of motor-neurone disease (progressive muscular atrophy).

Case 2.—An electrician, aged 24, complained that he could not hold a screwdriver because of weakness of the right hand which had begun four months previously; his left hand was also becoming weak. He had noticed some difficulty with speech for two and a half months and had slight pain in both knees. He had lost a stone in weight and had had a severe attack of tonsillitis three months previously.

On examination he was found to have dysarthria; weakness of the left side of the soft palate; bilateral wasting and fibrillation of the tongue; weakness and wasting of all muscles of the hands, arms, and forearms, more pronounced on the right side; arm-jerks brisk; continuous fasciculation in the right arm and shoulder muscles; no wasting or weakness of the lower limbs, but tone increased; knee and ankle jerks much exaggerated; plantar reflexes flexor; and ankle-clonus present on both sides.

Electromyography.—Surface electrodes on the right biceps and on the tongue revealed fasciculation potentials (fig. 6).

International Dental Congress

The 11th International Dental Congress of the Fédération Dentaire Internationale will take place in London from July 19 to 26, 1952, under the presidency of Dr. Wilfred Fish. Further information may be had from the organising secretary, 13, Hill Street, London, W.1.

St. Thomas's Hospital Musical Society

This society will perform Faure's requiem, and anthems by Weelkes, Gibbons, and Purcell in St. Sepulchre's Church, Holborn, on Tuesday, May 23, at 8.30 P.M. The conductor will be Dr. W. Dykes Bower, and the organist Mr. J. Dykes Bower, D.MUS. No tickets are required.

Newsholme Lectures

These lectures were endowed by the late Sir Arthur Newsholme, and Sir Henry Cohen will deliver the first course at the London School of Hygiene, Keppel Street, W.C.1, on May 22, 23, and 24, at 6.15 P.M. His subject is to be the Clinical Contribution to Public Welfare. Dr. H. P. Newsholme will take the chair at the first lecture.

W.H.O. Antibiotics Programme

The W.H.O. expert committee on antibiotics, which met in Geneva last month under the chairmanship of Mr. E. B. Chain, PH.D., F.R.S., recommended that the organisation should sponsor antibiotic research programmes and grant fellowships for long-term research. Several institutes, it was proposed, should be asked to provide research and training facilities. The committee proposed, too, that type culture collections should be deposited in certain institutions; and the scientific abstracting services should be asked to publish a combined issue containing abstracts of all available reports on antibiotics. The committee expressed the opinion that W.H.O. should organise controlled investigations of new drugs.

Presentation to Prof. Carl Browning

On April 28 a bronze bust of himself was presented to Prof. Carl Browning, F.R.S., on his retirement from the chair of bacteriology in the University of Glasgow, which he has held for 30 years. In making the presentation Sir Robert Muir, F.R.S., said: "Many teachers of the present day would benefit if they knew both what bacteriology was and how much Browning thought it necessary to teach the ordinary medical student. If they cut their courses accordingly I think it would be of great importance in the medical curriculum." The bust, which was executed by Mr. Benno Schotz, R.S.A., was afterwards accepted by the university for inclusion in their fine arts collection. Prof. D. F. Cappell presented Mrs. Browning with a gift of cutlery.

Committee on Internal Administration of Hospitals

The Central Health Services Council has appointed a committee, with 17 members, "to consider and report on the existing methods of administration in individual hospitals with particular reference to (1) matters of finance, staff, and supplies; (2) the extent to which differences in the work undertaken at different hospitals call for differences in their administrative organisation; and (3) the extent to which administrative duties should be undertaken by medical and nursing staff." Alderman Bradbeer is the chairman, and the medical members are Sir Ernest Rock Carling, Dr. A. A. Cunningham, Dr. H. G. Dain, Dr. W. G. Masefield, Dr. J. R. Murray, and Dr. J. Watt. Any person or body wishing to submit evidence should give notice to the joint secretaries of the Committee, Room 28, First Floor, Ministry of Health, S.W.1.

Retirement of Dr. M. C. Hogarth

Dr. Margaret Hogarth is to retire on June 30 from her post as a senior medical officer in the public-health department of the L.C.C.

Dr. Hogarth has served with the council since 1912, except for a period between 1925 and 1929 when she held an appointment at the Ministry of Health. In 1929 she surveyed district nursing in London; and her recommendations dealing [illegible] and general conditions were accepted as a sta[illegible] country. When appointed, in 1931, as a [illegible] medical officer, she was engaged on school health work. Later, as a divisional medical officer, she was in charge of the northern division of the council's school health service, and subsequently became responsible for residential nursery and residential school work. In 1937 she served as the Government representative on the Nutrition Committee of the League of Nations. Later that year she took charge of the counci[illegible] midwifery service under the Midwives Act, 1936. [illegible] he National Health Service Dr. Hogarth took [illegible] transferred from the Metropolitan boroughs, including supervision of maternity and child-welfare services.

Appointments

Carpenter, W. H. K., M.B. Brist.: deputy medical superintendent, Stoke Park Colony, Stapleton, Bristol.

Edge, May, M.B. *Glasg.*, D.P.H.: *asst. county* M.O., *North-West* Kent.

Gold, S. C., M.A., M.B. Camb., M.R.C.P.: asst. physician, skin department, St [illegible] don, and consultant dermatologist, [illegible] nd senior lecturer in dermatology at [illegible] School.

Graf, K. A., M.D. Vienna, D.P.M.: asst. psychiatrist (S.H.M.O.), Brentwood Mental Hospital.

Griffin, B. P., M.A. Camb., M.R.C.S.: deputy medical superintendent, Hortham Colony, Almondsbury, Bristol.

Hesling, A. G., M.B. Lond., M.R.C.P., D.C.H.: consultant pædiatrician, Blackpool and Preston hospital centres.

Lee, Constance, M.B. Lpool, D.OBST.: asst. M.O., maternity and child welfare, Manchester.

*Lochhead, Helenor, M.B. Edin.: house-physician, Hospital for Sick Children, Great Ormond Street, London.

McCaughan, D. V., M.B. Belf.: consultant ear, nose, and throat surgeon, Antrim, Ballymoney, Ballymena, Larne, and Magherafelt, Northern Ireland.

MacKeith, S. A., O.B.E., M.R.C.S., D.P.M.: consultant psychiatrist, Hellesdon Mental Hospital.

McKirdy, A. A., M.B. Glasg., M.R.C.O.G.: surgical officer (B1), gynæcological unit, Stoke Mandeville Hospital.

Montuschi, Elio, M.D. Florence, M.R.C.P.: physician, Italian Hospital, London.

Raffle, P. A. B., M.D. Lond., D.P.H., D.I.H.: senior asst. M.O., London Transport.

Savage, O. A., O.B.E., M.R.C.P.: consultant, rheumatism department, West London Hospital.

Steiner, R. E., M.B. N.U.I., D.M.R.: radiologist, department of radiodiagnosis, Hammersmith Hospital.

Turner, J. G. S., C.M.G., M.B., B.SC. Glasg., D.T.M., D.P.H.: asst. county M.O. and M.O.H. no. 4 health area, Cornwall.

Willey, C. B. I., M.B.E., M.C., M.A., B.M. Oxfd, M.R.C.P.: senior registrar in general medicine, Norfolk and Norwich Hospital.

* Amended notice.

VALUE OF ELECTROMYOGRAPHY IN CLINICAL NEUROLOGY

FRANK SARGENT
M.D. Lond., M.R.C.P.
SENIOR REGISTRAR, WEST END HOSPITAL FOR NERVOUS DISEASES; REGISTRAR, ELECTRODIAGNOSTIC SECTION, ST. THOMAS'S HOSPITAL; NEUROLOGIST, ST. STEPHEN'S HOSPITAL, CHELSEA

THE application of electromyography is limited to the lower motor neurones and the voluntary muscles. Although still in the experimental stage this method of investigation can supply information which may be of considerable importance in the solution of certain neurological problems. As with electrocardiography in heart-disease and radiography in pulmonary disease, electromyography should be used as an aid to diagnosis only after full and careful clinical examination. Without a clear clinical picture in his mind the physician may often find machines more misleading than useful in any branch of medicine.

Beginning as an experimental method in the physiological laboratory, electromyography was applied with great success in the diagnosis and prognosis of peripheral nerve injuries during the war. It has now been developed to a point where it can be relied on for special information in a wide range of everyday neurological disorders.

A brief description of some of the phenomena encountered in electromyography is necessary, but for a full description of all the reactions and relevant theories the reader is referred to the many excellent articles that Buchtal (1949) mentions in the report of the International Neurological Congress. Technical details of apparatus and its operation are beyond the scope of this communication; they, also, can be found in the various contributions that have appeared (Tyler 1950, Richardson 1950).

Maximal contraction of normal voluntary muscle produces a low-pitched rumble in the loud-speaker, and a sustained interference pattern on the cathode-ray screen (fig. 1). This pattern may be modified and attenuated by disease or injury until discrete motor-unit potentials only are seen (fig. 2), and, finally, no spikes at all appear on the screen and the loud-speaker is silent. Normal muscle is silent at rest.

Fibrillation in denervated muscle is seen on the screen as rhythmically repetitive potentials (fig. 3) of short duration and small amplitude (1–2 millisec., 50 μV) and is demonstrated as regular staccato ticking in the loud-speaker.

Synchronisation means the simultaneous occurrence of potentials from separate electrodes in different parts of the muscle on minimal contraction; such potentials are large—i.e., about 5–10 millisec. and up to 200 μV (fig. 4). Opinions differ about the cause of synchronisation, but all workers agree that it is seen so often in association with diseases of the spinal cord—e.g., anterior poliomyelitis—that it may be taken as strong evidence of a lesion affecting the anterior-horn cells.

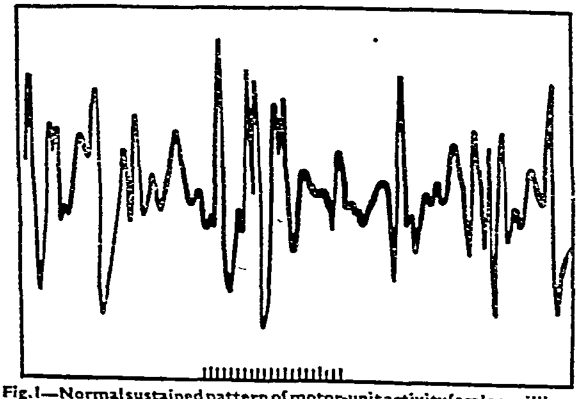

Fig. 1—Normal sustained pattern of motor-unit activity (scale: millisec.).

Other terms in common use will be explained below as they arise.

As Bauwens (1948) has pointed out, electromyographic examination should always be preceded by muscle-testing with a suitable rectangular-wave stimulator, because a combination of the two procedures gives a much more complete picture than either alone, and often indicates which muscles demand investigation. The plotting of an intensity-duration curve (fig. 5) has now taken the place of the "reaction of degeneration" test.

The cases described here all presented some point of doubt or difficulty which was considerably clarified by electromyography. For convenience of discussion the cases are grouped anatomically.

SPINAL CORD

Case 1.—A retired tailor, aged 74, complained of weakness of both arms and legs of gradual onset during the preceding eighteen months with pins-and-needles in the hands.

On examination there was gross wasting and weakness of deltoid, spinati, biceps, triceps, brachioradialis and flexors and extensors of wrist on both sides. The small muscles of the hands were not affected. Arm-jerks were normal except for a slight exaggeration of the triceps-jerks. Knee and ankle jerks were normal, the plantar reflexes were flexor, and the abdominal reflexes were present. No fasciculation was seen. Radiography of the cervical spine showed some osteo-arthritis. Total protein in the cerebrospinal fluid (C.S.F.) was 60 mg. per 100 ml.; the fluid was otherwise normal.

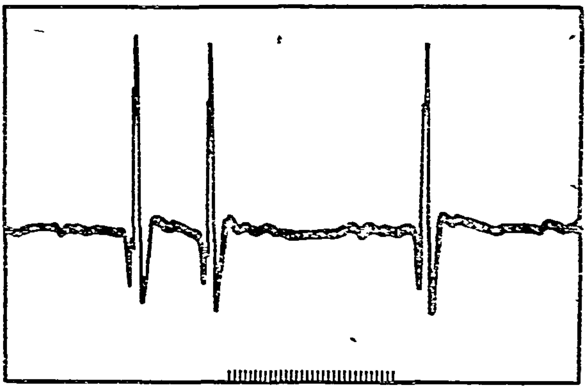

Fig. 2—Discrete motor-unit activity (scale: millisec.).

Muscle-testing revealed complete denervation (fig. 5c) of left deltoid.

Electromyography.—Needle electrodes showed decreased motor-unit activity on volition in left biceps and extensor digitorum communis, with definite synchronisation in these two muscles; and fibrillation potentials were detected in the extensor digitorum communis at rest.

Diagnosis.—These findings were considered to be compatible with a diagnosis of motor-neurone disease (progressive muscular atrophy).

Case 2.—An electrician, aged 24, complained that he could not hold a screwdriver because of weakness of the right hand which had begun four months previously; his left hand was also becoming weak. He had noticed some difficulty with speech for two and a half months and had slight pain in both knees. He had lost a stone in weight and had had a severe attack of tonsillitis three months previously.

On examination he was found to have dysarthria; weakness of the left side of the soft palate; bilateral wasting and fibrillation of the tongue; weakness and wasting of all muscles of the hands, arms, and forearms, more pronounced on the right side; arm-jerks brisk; continuous fasciculation in the right arm and shoulder muscles; no wasting or weakness of the lower limbs, but tone increased; knee and ankle jerks much exaggerated; plantar reflexes flexor; and ankle-clonus present on both sides.

Electromyography.—Surface electrodes on the right biceps and on the tongue revealed fasciculation potentials (fig. 6).

International Dental Congress

The 11th International Dental Congress of the Fédération Dentaire Internationale will take place in London from July 19 to 26, 1952, under the presidency of Dr. Wilfred Fish. Further information may be had from the organising secretary, 13, Hill Street, London, W.1.

St. Thomas's Hospital Musical Society

This society will perform Faure's requiem, and anthems by Weelkes, Gibbons, and Purcell in St. Sepulchre's Church, Holborn, on Tuesday, May 23, at 8.30 P.M. The conductor will be Dr. W. Dykes Bower, and the organist Mr. J. Dykes Bower, D.MUS. No tickets are required.

Newsholme Lectures

These lectures were endowed by the late Sir Arthur Newsholme, and Sir Henry Cohen will deliver the first course at the London School of Hygiene, Keppel Street, W.C.1, on May 22, 23, and 24, at 6.15 P.M. His subject is to be the Clinical Contribution to Public Welfare. Dr. H. P. Newsholme will take the chair at the first lecture.

W.H.O. Antibiotics Programme

The W.H.O. expert committee on antibiotics, which met in Geneva last month under the chairmanship of Mr. E. B. Chain, PH.D., F.R.S., recommended that the organisation should sponsor antibiotic research programmes and grant fellowships for long-term research. Several institutes, it was proposed, should be asked to provide research and training facilities. The committee proposed, too, that type culture collections should be deposited in certain institutions; and the scientific abstracting services should be asked to publish a combined issue containing abstracts of all available reports on antibiotics. The committee expressed the opinion that W.H.O. should organise controlled investigations of new drugs.

Presentation to Prof. Carl Browning

On April 28 a bronze bust of himself was presented to Prof. Carl Browning, F.R.S., on his retirement from the chair of bacteriology in the University of Glasgow, which he has held for 30 years. In making the presentation Sir Robert Muir, F.R.S., said: "Many teachers of the present day would benefit if they knew both what bacteriology was and how much Browning thought it necessary to teach the ordinary medical student. If they cut their courses accordingly I think it would be of great importance in the medical curriculum." The bust, which was executed by Mr. Benno Schotz, R.S.A., was afterwards accepted by the university, for inclusion in their fine arts collection. Prof. D. F. Cappell presented Mrs. Browning with a gift of cutlery.

Committee on Internal Administration of Hospitals

The Central Health Services Council has appointed a committee, with 17 members, "to consider and report on the existing methods of administration in individual hospitals with particular reference to (1) matters of finance, staff, and supplies; (2) the extent to which differences in the work undertaken at different hospitals call for differences in their administrative organisation; and (3) the extent to which administrative duties should be undertaken by medical and nursing staff." Alderman Bradbeer is the chairman, and the medical members are Sir Ernest Rock Carling, Dr. A. A. Cunningham, Dr. H. G. Dain, Dr. W. G. Masefield, Dr. J. R. Murray, and Dr. J. Watt. Any person or body wishing to submit evidence should give notice to the joint secretaries of the Committee, Room 28, First Floor, Ministry of Health, S.W.1.

Retirement of Dr. M. C. Hogarth

Dr. Margaret Hogarth is to retire on June 30 from her post as a senior medical officer in the public-health department of the L.C.C.

Dr. Hogarth has served with the council since 1912, except for a period between 1925 and 1929 when she held an appointment at the Ministry of Health. In 1929 she surveyed district nursing in London; and her recommendations dealing with staffing, nursing, and general conditions were accepted as a standard throughout the country. When appointed, in 1931, as a whole-time assistant medical officer, she was engaged on school health work. Later, as a divisional medical officer, she was in charge of the northern division of the council's school health service, and subsequently became responsible for residential nursery and residential school work. In 1937 she served as the Government representative on the Nutrition Committee of the League of Nations. Later that year she took charge of the council's domiciliary midwifery service under the Midwives Act, 1936. With the inception of the National Health Service Dr. Hogarth took over some of the duties transferred from the Metropolitan boroughs, including supervision of maternity and child-welfare services.

Appointments

Carpenter, W. H. K., M.B. Brist.: deputy medical superintendent, Stoke Park Colony, Stapleton, Bristol.

Edge, May, M.B. Glasg., D.P.H.: asst. county M.O., North-West Kent.

Gold, S. C., M.A., M.B. Camb., M.R.C.P.: asst. physician, skin department, St. George's Hospital, London, and consultant dermatologist, Hammersmith Hospital, and senior lecturer in dermatology at the Postgraduate Medical School.

Graf, K. A., M.D. Vienna, D.P.M.: asst. psychiatrist (S.H.M.O.), Brentwood Mental Hospital.

Griffin, B. P., M.A. Camb., M.R.C.S.: deputy medical superintendent, Hortham Colony, Almondsbury, Bristol.

Hesling, A. G., M.B. Lond., M.R.C.P., D.C.H.: consultant pædiatrician, Blackpool and Preston hospital centres.

Lee, Constance, M.B. Lpool, D.OBST.: asst. M.O., maternity and child welfare, Manchester.

*Lochhead, Helenor, M.B. Edin.: house-physician, Hospital for Sick Children, Great Ormond Street, London.

McCaughan, D. V., M.B. Belf.: consultant ear, nose, and throat surgeon, Antrim, Ballymoney, Ballymena, Larne, and Magherafelt, Northern Ireland.

MacKeith, S. A., O.B.E., M.R.C.S., D.P.M.: consultant psychiatrist, Hellesdon Mental Hospital.

McKirdy, A. A., M.B. Glasg., M.R.C.O.G.: surgical officer (B1), gynæcological unit, Stoke Mandeville Hospital.

Montuschi, Elio, M.D. Florence, M.R.C.P.: physician, Italian Hospital, London.

Raffle, P. A. B., M.D. Lond., D.P.H., D.I.H.: senior asst. M.O., London Transport.

Savage, O. A., O.B.E., M.R.C.P.: consultant, rheumatism department, West London Hospital.

Steiner, R. E., M.B. N.U.I., D.M.R.: radiologist, department of radiodiagnosis, Hammersmith Hospital.

Turner, J. G. S., C.M.G., M.B., B.SC. Glasg., D.T.M., D.P.H.: asst. county M.O. and M.O.H. no. 4 health area, Cornwall.

Willey, C. B. I., M.B.E., M.C., M.A., B.M. Oxfd, M.R.C.P.: senior registrar in general medicine, Norfolk and Norwich Hospital.

* Amended notice.

Births, Marriages, and Deaths

BIRTHS

Dobree.—On April 29, in London, the wife of Mr. John Dobree, M.S.—a son.

Gauld.—On April 29, the wife of Dr. G. O. Gauld—a daughter.

Gill.—On April 30, at Godalming, the wife of Mr. W. G. Gill, F.R.C.S.—a son.

Glaser.—On May 4, at Cambridge, the wife of Dr. M. Glaser—a daughter.

Gurling.—On May 6, the wife of Dr. Kenneth Gurling—a son.

Harcourt.—On April 23, in London, the wife of Dr. R. G. Harcourt—a daughter.

Hutchison.—On May 1, the wife of Mr. J. B. Hutchison, F.R.C.S.—a son.

Johnson.—On May 4, the wife of Dr. Peter Johnson—a son.

Jones.—On May 3, in London, the wife of Mr. H. O. Jones, F.R.C.S.—a daughter.

Lutton.—On April 28, at Ashton-on-Mersey, the wife of Dr. R. A. Lutton—a son.

Wetherell.—On May 4, at Birkenhead, the wife of Dr. Geoffrey Wetherell—a son.

Wright.—On April 29, in London, the wife of Dr. John Wright—a son.

MARRIAGES

Beswick—Welch.—On April 29, at Over Whitacre, Joseph Hubert Beswick, M.B., to Sylvia Joan Welch.

Mayne—Doy.—On May 6, at Brighton, Cyril Frederick Mayne, O.B.E., F.R.C.S., to Gladys Lillian Doy.

DEATHS

Burnett.—On April 28, at West Worthing, Frank Marsden Burnett, M.D. Lond., D.P.H., aged 80.

Corner.—On May 2, at Beaconsfield, Edred Moss Corner, M.A., M.B., M.CHIR. Camb., B.SC. Lond., F.R.C.S.

Edwards.—On May 4, at Bromley, Frederic William Edwards, M.R.C.S., aged 80.

Galt.—On May 4, William James Galt, M.A., B.M. Oxfd.

Gellatly.—On May 6, at Bramhall, Cheshire, David Gilbert Gellatly, L.R.C.P.E., aged 72.

Goodfellow.—On May 1, at Chesterfield, James Anderson Goodfellow, M.B. Glasg., aged 85.

Gray.—On May 1, at Driffield, Yorks, Thomas Gray, M.B. Glasg., aged 34.

Hay[illegible] Liverpool on May 2, Ronald John Gwynne [illegible] R.C.S., aged 38.

Low[illegible] Lancaster, Richard Charles Lowther, M.B. Edin.

Mackworth.—On May 3, at Dyce, Aberdeenshire, Norman Walter Mackworth, M.B. Aberd., F.R.C.S.E., lieut.-colonel, I.M.S. retd.

McLeay.—On April 30, Charles William McLeay, B.A., M.D. West. Univ. Ont., D.P.H.

Pike.—On May 6, in London, Douglas Reginald Pike, M.A., B.M. Oxfd.

Mr. Victor Bonney has been elected an honorary fellow of the Association of Surgeons.

Prof. John McMichael, under the auspices of the British Council, is making a lecture tour during May in Denmark, Sweden, Finland, and Norway at the invitation of Scandinavian medical organisations.

VALUE OF ELECTROMYOGRAPHY IN CLINICAL NEUROLOGY

FRANK SARGENT
M.D. Lond., M.R.C.P.
SENIOR REGISTRAR, WEST END HOSPITAL FOR NERVOUS DISEASES; REGISTRAR, ELECTRODIAGNOSTIC SECTION, ST. THOMAS'S HOSPITAL; NEUROLOGIST, ST. STEPHEN'S HOSPITAL, CHELSEA

THE application of electromyography is limited to the lower motor neurones and the voluntary muscles. Although still in the experimental stage this method of investigation can supply information which may be of considerable importance in the solution of certain neurological problems. As with electrocardiography in heart-disease and radiography in pulmonary disease, electromyography should be used as an aid to diagnosis only after full and careful clinical examination. Without a clear clinical picture in his mind the physician may often find machines more misleading than useful in any branch of medicine.

Beginning as an experimental method in the physiological laboratory, electromyography was applied with great success in the diagnosis and prognosis of peripheral nerve injuries during the war. It has now been developed to a point where it can be relied on for special information in a wide range of everyday neurological disorders.

A brief description of some of the phenomena encountered in electromyography is necessary, but for a full description of all the reactions and relevant theories the reader is referred to the many excellent articles that Buchtal (1949) mentions in the report of the International Neurological Congress. Technical details of apparatus and its operation are beyond the scope of this communication; they, also, can be found in the various contributions that have appeared (Tyler 1950, Richardson 1950).

Maximal contraction of normal voluntary muscle produces a low-pitched rumble in the loud-speaker, and a sustained interference pattern on the cathode-ray screen (fig. 1). This pattern may be modified and attenuated by disease or injury until discrete motor-unit potentials only are seen (fig. 2), and, finally, no spikes at all appear on the screen and the loud-speaker is silent. Normal muscle is silent at rest.

Fibrillation in denervated muscle is seen on the screen as rhythmically repetitive potentials (fig. 3) of short duration and small amplitude (1–2 millisec., 50 μV) and is demonstrated as regular staccato ticking in the loud-speaker.

Synchronisation means the simultaneous occurrence of potentials from separate electrodes in different parts of the muscle on minimal contraction; such potentials are large—i.e., about 5–10 millisec. and up to 200 μV (fig. 4). Opinions differ about the cause of synchronisation, but all workers agree that it is seen so often in association with diseases of the spinal cord—e.g., anterior poliomyelitis—that it may be taken as strong evidence of a lesion affecting the anterior-horn cells.

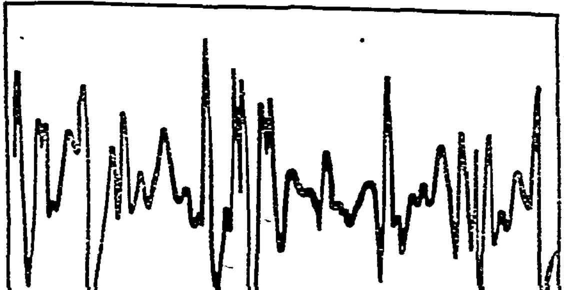

Fig. 1—Normal sustained pattern of motor-unit activity (scale: millisec.).

Other terms in common use will be explained below as they arise.

As Bauwens (1948) has pointed out, electromyographic examination should always be preceded by muscle-testing with a suitable rectangular-wave stimulator, because a combination of the two procedures gives a much more complete picture than either alone, and often indicates which muscles demand investigation. The plotting of an intensity-duration curve (fig. 5) has now taken the place of the "reaction of degeneration" test.

The cases described here all presented some point of doubt or difficulty which was considerably clarified by electromyography. For convenience of discussion the cases are grouped anatomically.

SPINAL CORD

Case 1.—A retired tailor, aged 74, complained of weakness of both arms and legs of gradual onset during the preceding eighteen months with pins-and-needles in the hands.

On examination there was gross wasting and weakness of deltoid, spinati, biceps, triceps, brachioradialis and flexors and extensors of wrist on both sides. The small muscles of the hands were not affected. Arm-jerks were normal except for a slight exaggeration of the triceps-jerks. Knee and ankle jerks were normal, the plantar reflexes were flexor, and the abdominal reflexes were present. No fasciculation was seen. Radiography of the cervical spine showed some osteo-arthritis. Total protein in the cerebrospinal fluid (C.S.F.) was 60 mg. per 100 ml.; the fluid was otherwise normal.

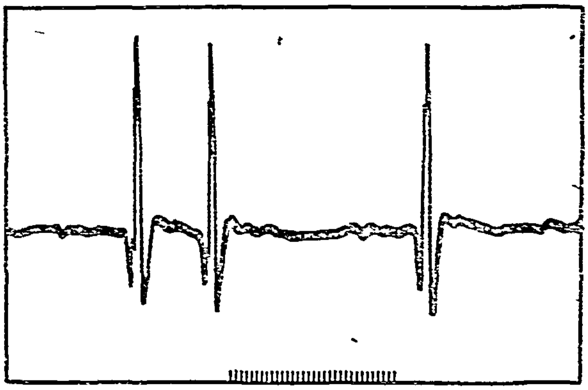

Fig. 2—Discrete motor-unit activity (scale: millisec.).

Muscle-testing revealed complete denervation (fig. 5c) of left deltoid.

Electromyography.—Needle electrodes showed decreased motor-unit activity on volition in left biceps and extensor digitorum communis, with definite synchronisation in these two muscles; and fibrillation potentials were detected in the extensor digitorum communis at rest.

Diagnosis.—These findings were considered to be compatible with a diagnosis of motor-neurone disease (progressive muscular atrophy).

Case 2.—An electrician, aged 24, complained that he could not hold a screwdriver because of weakness of the right hand which had begun four months previously; his left hand was also becoming weak. He had noticed some difficulty with speech for two and a half months and had slight pain in both knees. He had lost a stone in weight and had had a severe attack of tonsillitis three months previously.

On examination he was found to have dysarthria; weakness of the left side of the soft palate; bilateral wasting and fibrillation of the tongue; weakness and wasting of all muscles of the hands, arms, and forearms, more pronounced on the right side; arm-jerks brisk; continuous fasciculation in the right arm and shoulder muscles; no wasting or weakness of the lower limbs, but tone increased; knee and ankle jerks much exaggerated; plantar reflexes flexor; and ankle-clonus present on both sides.

Electromyography.—Surface electrodes on the right biceps and on the tongue revealed fasciculation potentials (fig. 6).

Needle electrodes in the right biceps revealed a normal sustained interference pattern on volition, and at rest there were spontaneous polyphasic potentials; in the extensors of the left wrist *volitional contraction produced only* discrete motor-unit activity.

Diagnosis: myelopathic lesion in anterior-horn cells—motor-neurone disease.

The diagnosis of motor-neurone disease in these two cases was fairly obvious, but there were some unusual clinical features in each. In case 1 there were the late onset, absence of fasciculation, sparing of the small muscles of the hands, and the slight increase of total protein in the C.S.F. In case 2 there were the onset at rather an early age, the possible relation to infection, and the rapid progress and widespread distribution. The electrical examination provided evidence that was sufficiently convincing to confirm the diagnosis. If fasciculation potentials can be demonstrated they suggest strongly that anterior-horn cells are being slowly destroyed; it happened in these two cases that the electromyograph gave no more information about fasciculation than was available clinically—i.e., its absence in case 1 and its presence in case 2. Not infrequently, however, fasciculation can be detected readily on electrical examination when it is imperceptible on clinical observation. The presence of fibrillation merely indicated that there was a degree of denervation in the muscles tested (additional evidence of this was provided by the rectangular-wave stimulator in case 1); but synchronisation placed the lesion in the anterior-horn cells.

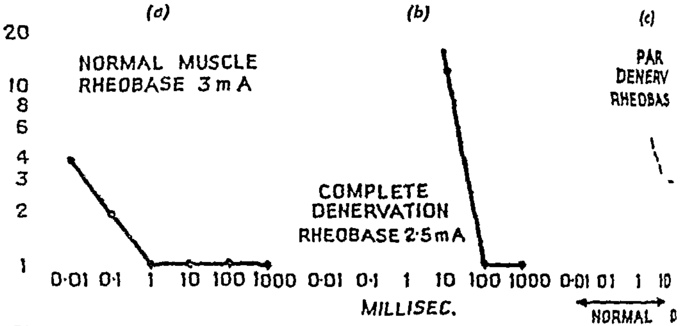

Fig. 5—Intensity-duration curves; muscle-testing with rectangular-wave sti

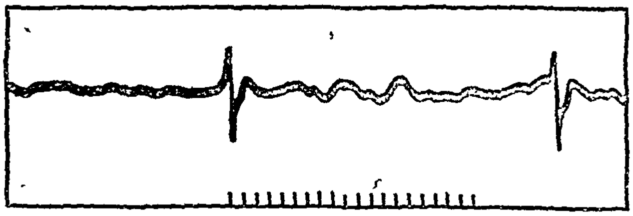

Fig. 3—Fibrillation potentials (scale: millisec.).

Case 3.—A draper's assistant, aged 17, complained of pain in his left knee when standing at the counter, together with weakness and wasting of the left thigh since childhood. He had had an illness, presumed to be acute poliomyelitis, at the age of 12 months during an epidemic in La Linea.

On examination there were nystagmoid jerks, more pronounced on looking to the left than to the right; some unsteadiness of the left hand on performing the finger-nose test; wasting and weakness of all muscles of the left thigh; bilateral pes cavus; and no sensory changes. No family history of nervous disorder could be obtained.

Muscle-testing.—The intensity-duration curve in the left rectus femoris was normal (fig. 5*a*).

Electromyography.—Needle electrodes inserted to
muscle revealed a reduced pattern of motor-unit
on minimal voluntary contraction defin secretaries
appeared. istry of Health,

Diagnosis: anterior-horn le
poliomyelitis.

Case 4.—A boy, aged re on June 30 from her post
we previously held the public-health department of
senior medic
he L.C.C.

Dr. Hogarth has served with the council since 1912, except for period between 1923 and 1929 when she held an appointment at he Ministry of Health. In 1929 she surveyed district nursing in ondon; and her recommendations dealing with staffing, nursing, nd general conditions were accep
ountry. When appointed, in
edical officer, she was engaged
divisional medical officer, she
ivision of the council's school
ecame responsible for residenti
vork. In 1937 she served as the

under the Midwives Act, 1936.
Health Service Dr. Hogarth took
rom the Metropolitan boroughs, including supervision of materni
nd child-welfare services.

reduced to a discrete pattern, with polyphasic pot rapid fatigue, and definite synchronisation; at rest th spontaneous fibrillation potentials in this muscle.

Diagnosis.—Electrical examination confirmed the d of anterior poliomyelitis, affecting especially the right compartment muscles and peronei. A month later, stim of the right lateral popliteal nerve at the knee el response from the extensor hallucis longus as well tibialis anticus; the findings were otherwise the sa on the first occasion.

Synchronisation in the paralysed muscles of these patients pointed to a myelopathic lesion, almost cert anterior poliomyelitis, and this result coincided wit clinical histories. It was of considerable help to this point, because case 3, the young man with wasted thigh, resembled a *forme fruste* of Friedr ataxia, and the absence of a reliable family hi rendered the problem more obscure. When it demonstrated that the thigh muscles had atrop because of poliomyelitis, the other symptoms could be ascribed to the same cause. In case 4, the boy foot-drop, it was possible not only to confirm the nat of the infection but also to state which muscles w affected, with much more precision than was possi clinically, and finally, by means of successive exami tions, to forecast the amount of recovery that could expected.

Case 5.—A clerk, aged 40, had gradually lost power in hands for two years; at the same time he had noticed of appreciation of heat and cold in his right leg.

On examination he had nystagmus, diminution of pain sensation in the left hand, loss of pain and temperature sense from the right hip downwards, fasciculation in the chest muscles and left hand, poor grip in the right hand, increase of all tendon-jerks, extensor plantar responses and absent abdominal reflexes. The C.S.F. yril Frederick Mayne,
test showed a slow m Doy.

DEATHS

pril 28, at West Worthing, Frank Marsden Burnett, nd., D.P.H., aged 80.

NER.—On May 2, at Beaconsfield, Edred Moss Corner, M.A., M.B., M.CHIR. Camb., B.SC. Lond., F.R.C.S.

EDWARDS.—On May 4, at Bromley, Frederic William Edwards, M.R.C.S., aged 80.

GALT.—On May 4, William James Galt, M.A., B.M. Oxfd.

GELLATLY.—On May 6, at Bramhall, Cheshire, David Gilbert Gellatly, L.R.C.P.E., aged 72.

GOODFELLOW.—On May 1, at Chesterfield, James Anderson Goodfellow, M.B. Glasg., aged 85.

GRAY.—On May 1, at Driffield, Yorks, Thomas Gray, M.B. Glasg., aged 34.

HAYTON-WILLIAMS.—At Liverpool on May 2, Ronald John Gwynne Hayton-Williams, L.D.S. R.C.S., aged 38.

LOWTHER.—On April 30, at Lancaster, Richard Charles Lowther, M.B. Edin.

Norman Walter
MACKWORTH.—On May 3, at I.M.S. retd.
Mackworth, M.B. Aberd., A., M.D. West.

MCLEAY.—On April 30, Char
Univ. Ont., D.P.H.

PIKE.—On May 6, in London, Douglas Reginald Pike, M.A., B.M. Oxfd.

Mr. Victor Bonney has been elected an honorary fellow of the Association of Surgeons.

Prof. John McMichael, under the auspices of the Briti Council, is making a lecture tour during May in Denmar Sweden, Finland, and Norway at the invitation Scandinavian medical organisations.

Electromyography.—Needle electrodes were inserted into the left thenar and right hypothenar muscles and the flexors of the forearms. On volition motor-unit activity was decreased in the left thenar eminence; it was discrete in the right hypothenar eminence, and here spontaneous fibrillation potentials were present at rest; in the flexor muscles of the left forearm motor-unit activity was decreased and there was definite synchronisation (fig. 4).

Diagnosis.—These findings pointed to a disease of the spinal cord, which justified the diagnosis of syringomyelia.

Case 6.—A male student, aged 27, presented with four years' history of weakness of the left hand and leg and two months' history of loss of sensation on the left side of the face and neck.

On examination he had Horner's syndrome on the left side; loss of pain and light touch sense in the area of C2–C4 segments, with variable thermal sense but no true dissociated anæsthesia; hyperæsthesia just below the clavicles; diminution of vibration sense in the left arm and leg; gross wasting of the left shoulder-girdle muscles, slight wasting of the left deltoid and all muscles of the left upper limb, including the hand; a completely powerless left arm; exaggerated knee and ankle jerks (left more than right); plantar reflexes extensor; abdominal reflexes absent; and fasciculation round the left shoulder. The C.S.F. contained 3 lymphocytes and total protein 220 mg. per 100 ml.

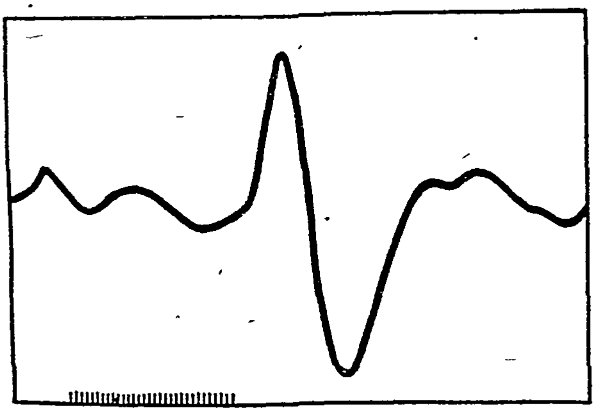

Fig. 6—Fasciculation potentials, diphasic wave, from surface electrodes (scale: millisec.).

Operation.—Laminectomy was subsequently performed; the spinal cord bulged when exposed and, when it was incised, tumour tissue welled up, which on biopsy proved to be that of glioblastoma multiforme; the tumour extended above and below the field of operation (C2–C4).

Electromyography with needle electrodes showed decreased motor-unit activity in most muscles of the left arm. There were polyphasic complex potentials (fig. 7) in the left deltoid and biceps; but no synchronisation was elicited.

Case 7.—A housewife, aged 56, was admitted with multiple bruises, hæmoptysis, and hæmatemesis, as a result of chronic lymphatic leukæmia. When the hæmorrhagic condition cleared she developed left foot-drop, and all forms of sensation were diminished in the left leg. She also complained of pain in the right leg; both legs were weak, particularly the muscles of the left anterior compartment.

Electromyography.—Needle electrodes were inserted into the left tibialis anticus. Motor-unit activity on volition was reduced, and there was synchronisation; spontaneous bursts of polyphasic discharges and fibrillation occurred at rest.

Diagnosis.—Both the spontaneous activity and synchronisation point to a myelopathic origin of the symptoms, and fibrillation indicates denervation.

These three cases are grouped together because all the patients had intramedullary lesions. The diagnosis of syringomyelia in case 5 was never in doubt, and the electromyograph was of use only to confirm the presence of anterior-horn lesions; it is described mainly for comparison with cases 6 and 7. In case 6 a spinal-cord tumour had already been diagnosed and operation performed before electromyography; but a subsequent investigation threw some light on the anatomical distribution of the lesions. It might have been expected that a case with lower motor-neurone lesions due to an intramedullary tumour would show synchronisation; the fact that it did not suggested that the wasting was due not to direct involvement of the anterior horns but to compression and kinking of the anterior roots consequent on the swelling of the cord. The polyphasic complex potentials were taken to mean that some recovery of function in these roots had followed decompression and deep X-ray therapy. The only point in doubt in case 7 was whether the hæmorrhages or leukæmic deposits causing the neurological lesions were within or outside the spinal cord; it is suggested that the presence of synchronisation pointed to a lesion in the substance of the cord, in the anterior horns, rather than external to the cord.

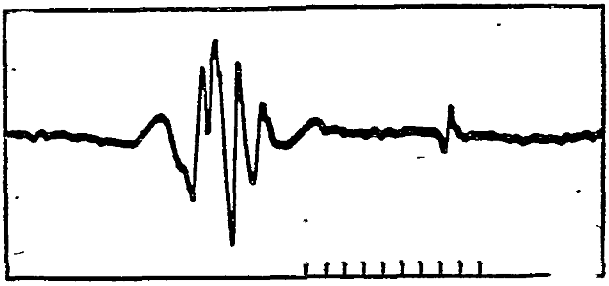

Fig. 7—Polyphasic complex "recovery" potential (scale: millisec.).

Electromyography did not afford any help in the treatment of these three patients, but it did throw some light on the pathological and anatomical pictures.

NERVE-ROOTS

Case 8.—A bricklayer, aged 38, complained of pain in the back of his neck, which had begun fairly suddenly twelve months before (he thought at the time that he must have sat in a draught); after a month the pain had radiated down the right arm to the wrist, back of hand, and fingers, which tingled; symptoms had persisted ever since without remission. The pain was aggravated by coughing; both rotating and inclining the head caused pain and tingling in the right arm. There was no demonstrable sensory loss, and power was unimpaired. Radiography of the cervical spine showed fusion of 4th and 5th vertebræ but no obvious cause for the pain. A "probably prolapsed intervertebral disc but not typical" was diagnosed. Manipulation and traction did not give any relief.

Electromyography.—The electromyograph was silent with surface electrodes on the right deltoid and biceps at rest, but on the triceps and extensor carpi radialis there were spontaneous rhythmic discharges strongly suggesting root irritation.

Diagnosis: pressure on the root of the 7th cervical nerve. At operation a small piece of prolapsed disc material was found in contact with the 7th cervical root and was removed. A month after the operation electromyographic examination was repeated, and the right triceps was now silent at rest.

Case 9.—A caterer's assistant, aged 60, complained of "agonising" pain down the outer border of his right arm as far as the hand. He sat in the outpatient department leaning over a couch with his head in his hands, moaning faintly.

On examination no evidence of organic disease was found. Radiography showed some lipping and beaking of the lower four cervical vertebræ, with osteophytic narrowing of the intervertebral foramina, but the changes were no more than are often seen in films of patients who make no complaint referable to the spinal cord or the nerve-roots. There was a strong suspicion that this patient's symptoms were largely psychogenic.

Electromyography.—When needle electrodes were inserted into the right deltoid, irritation potentials (spontaneous rhythmic spikes) (fig. 8) were seen; motor-unit activity on volition was within normal limits.

Diagnosis irritation of the 5th and 6th nerve-roots by osteo-arthritis of the vertebral column. Suitable physiotherapy relieved the symptoms.

Case 10.—A temporary civil servant, aged 46, had five months' history of weakness of the right hand; he had also experienced pins-and-needles in this hand for four years, although this symptom was not prominent. During the past

Needle electrodes in the right biceps revealed a normal sustained interference pattern on volition, and at rest there were spontaneous polyphasic potentials; in the extensors of the left wrist volitional contraction produced only discrete motor-unit activity.

Diagnosis: myelopathic lesion in anterior-horn cells—motor-neurone disease.

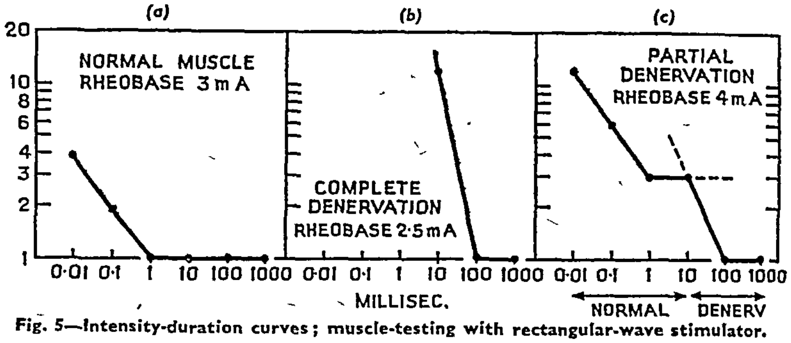

Fig. 5—Intensity-duration curves; muscle-testing with rectangular-wave stimulator.

The diagnosis of motor-neurone disease in these two cases was fairly obvious, but there were some unusual clinical features in each. In case 1 there were the late onset, absence of fasciculation, sparing of the small muscles of the hands, and the slight increase of total protein in the C.S.F. In case 2 there were the onset at rather an early age, the possible relation to infection, and the rapid progress and widespread distribution. The electrical examination provided evidence that was sufficiently convincing to confirm the diagnosis. If fasciculation potentials can be demonstrated they suggest strongly that anterior-horn cells are being slowly destroyed; it happened in these two cases that the electromyograph gave no more information about fasciculation than was available clinically—i.e., its absence in case 1 and its presence in case 2. Not infrequently, however, fasciculation can be detected readily on electrical examination when it is imperceptible on clinical observation. The presence of fibrillation merely indicated that there was a degree of denervation in the muscles tested (additional evidence of this was provided by the rectangular-wave stimulator in case 1); but synchronisation placed the lesion in the anterior-horn cells.

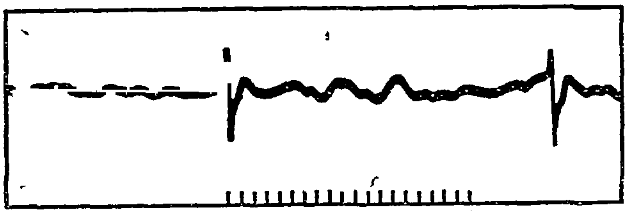

Fig. 3—Fibrillation potentials (scale: millisec.).

Case 3.—A draper's assistant, aged 17, complained of pain in his left knee when standing at the counter, together with weakness and wasting of the left thigh since childhood. He had had an illness, presumed to be acute poliomyelitis, at the age of 12 months during an epidemic in La Linea.

On examination there were nystagmoid jerks, more pronounced on looking to the left than to the right; some unsteadiness of the left hand on performing the finger-nose test; wasting and weakness of all muscles of the left thigh; bilateral pes cavus; and no sensory changes. No family history of nervous disorder could be obtained.

Muscle-testing.—The intensity-duration curve in the le rectus femoris was normal (fig. 5*a*).

Electromyography.—Needle electrodes inserted and muscle revealed a reduced pattern of motor-unit isation on minimal voluntary contraction defi resulting from appeared.

Diagnosis: anterior-horn les had right foot-drop. Seven poliomyelitis. vague febrile illness, followed

Case 4.—A boy, ag kness in his right leg. eviously h ed weakness and wasting of all the muscles of the right leg; there was trable sensory loss.

esting.—Stimulation of the left lateral popliteal the knee elicited a normal response in all the muscles d by this nerve, but on the right side the only muscle contracted was the tibialis anticus. No response was obtained from stimulation of the right medial popliteal nerve, but the tibialis posticus muscle could be stimulated directly at the ankle. The right tibialis anticus and *peronei contracted* sluggishly.

Electromyography.—Needle electrodes in the right tibialis anticus revealed that motor-unit activity on volition was reduced to a discrete pattern, with polyphasic potentials, rapid fatigue, and definite synchronisation; at rest there were spontaneous fibrillation potentials in this muscle.

Diagnosis.—Electrical examination confirmed the diagnosis of anterior poliomyelitis, affecting especially the right anterior-compartment muscles and peronei. A month later, stimulation of the right lateral popliteal nerve at the knee elicited a response from the extensor hallucis longus as well as the tibialis anticus; the findings were otherwise the same as on the first occasion.

Synchronisation in the paralysed muscles of these two patients pointed to a myelopathic lesion, almost certainly anterior poliomyelitis, and this result coincided with the clinical histories. It was of considerable help to settle this point, because case 3, the young man with the wasted thigh, resembled a *forme fruste* of Friedreich's ataxia, and the absence of a reliable family history rendered the problem more obscure. When it was demonstrated that the thigh muscles had atrophied because of poliomyelitis, the other symptoms could well be ascribed to the same cause. In case 4, the boy with foot-drop, it was possible not only to confirm the nature of the infection but also to state which muscles were affected, with much more precision than was possible clinically, and finally, by means of successive examinations, to forecast the amount of recovery that could be expected.

Case 5.—A clerk, aged 40, had gradually lost power in his hands for two years; at the same time he had noticed loss of appreciation of heat and cold in his right leg.

On examination he had nystagmus, diminution of pain sensation in the left hand, loss of pain and temperature sense from the right hip downwards, fasciculation in the chest muscles and left hand, poor grip in the right hand, increase of all tendon-jerks, extensor plant and absent abdominal reflexes. The C.S. mal, and Queckenstedt's test showed a slow and fall.

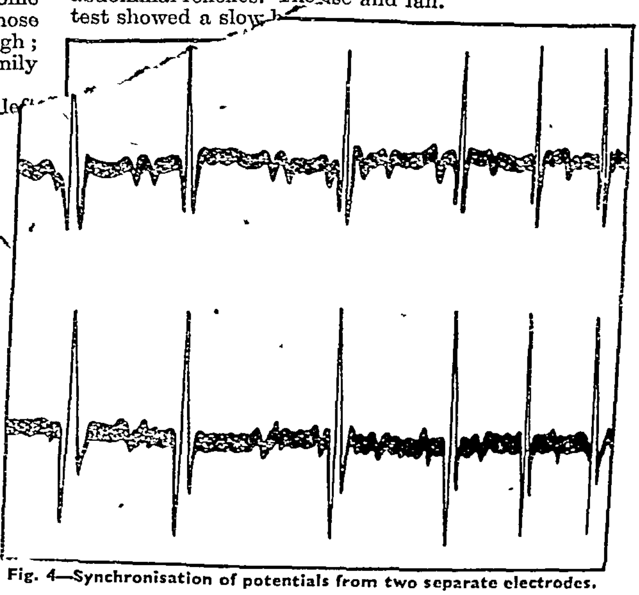

Fig. 4—Synchronisation of potentials from two separate electrodes.

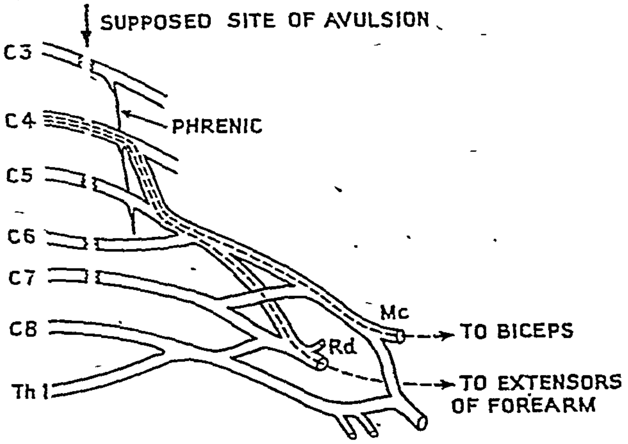

Fig. 9—Brachial plexus, showing path of regenerating fibres (dotted lines) intended for phrenic but actually reaching nerves to biceps and extensors of forearm : Mc, musculocutaneous ; Rd, radial.

Case 13.—A journeyman-carpenter, aged 18, had difficulty in holding his work with his left hand, because of weakness of the left arm from birth.

On examination he showed weakness and wasting of the trapezius, deltoid, spinati, biceps, triceps, brachioradialis, and wrist extensors, with wrist-drop ; the flexors of the wrist and the small muscles of the hand had escaped. The disability was far greater than was to be expected from the degree of wasting present. Rhythmical fasciculation was noted in the biceps, but its significance was not appreciated at the time. There was no sensory loss.

Muscle-testing.—It was possible to stimulate all the muscles of the arm, forearm, and hand electrically except the extensor carpi radialis.

Electromyography.—When needle electrodes were inserted into the left biceps, spontaneous motor-unit activity occurred in time with the respiration ; a similar phenomenon was noted in the extensor digitorum communis. No spontaneous activity was found in the right arm muscles. It was now obvious that the fasciculation referred to above was part and parcel of a response to a stimulus synchronous with respiration causing motor-unit activity which had been unmasked by the electromyograph. On volition all the muscles of the left arm and forearm except the extensor carpi radialis produced a normal sustained pattern of motor-unit activity, thus confirming the clinical observation that the disability was far in excess of what was to be anticipated from the condition of the muscles.

Diagnosis : birth injury to the brachial plexus, affecting all the cervical nerves from C3 to C7 ; crossed reinnervation, probably from roots of the phrenic nerve to nerves of supply to the biceps and extensor digitorum communis.

Some puzzling features in case 12 were the lapse of two years between the supposed trauma and the onset of symptoms, the radiological report, and the exact localisation of the lesion. The electrical investigation suggested that the lesion was in the brachial plexus (it was unlikely to be a prolapsed disc, because several roots were involved) ; the history of violence was inescapable ; and the radiological picture appeared to be more than a mere " red herring." The most probable explanation of this case is that a traction injury of the plexus started the trouble, but that it did not become severe enough to attract the patient's attention until some additional factor, possibly the osteo-arthritis, aggravated it sufficiently to cause actual disability.

Case 13 is an interesting example of crossed reinnervation. The types of birth palsy named after Erb and Klumpke are due to traction lesions of the upper and the lower parts of the brachial plexus respectively. This case, however, is one of a third type, in which most of the cervical nerves are involved and the lesion is situated close to the vertebral column. When regeneration took place, many of the down-growing fibres found their way into the wrong Schwann tubes. This is a well-known cause of residual disability in peripheral nerve injuries. In this case it was possible to demonstrate the crossed reinnervation, owing to the fact that some of the fibres originating from root C4, normally destined for the diaphragm via the phrenic nerve, had insinuated themselves into the musculocutaneous and musculospiral nerves and so reached the biceps and extensor digitorum communis muscles (fig. 9). It must be confessed that the correct diagnosis could have been made on clinical grounds alone, for, after the electromyograph had clearly shown the relationship between motor-unit activity in the biceps and the rhythm of respiration, the fasciculation was seen obviously to coincide with inspiration. Moreover, when a stethoscope was placed on the biceps, a harsh crackling sound was heard in time with respiration, in contrast with the normal rumbling sound on voluntary flexion of the elbow (Buchtal 1949). Nevertheless it was the electrical examination which pointed the way to the recognition of these facts and rendered the clinical picture more comprehensible.

PERIPHERAL NERVES

Case 14.—A porter, aged 64, had a complete right-sided facial palsy following an eruption with reddening and pain in the right ear. Repeated electrical examinations were made, but no conduction could be demonstrated in the facial nerve at its cranial exit, even after three months. Needle electrodes in the right frontalis, levator anguli oris, and mentalis showed no motor-unit activity at all on volition, but spontaneous fibrillation potentials at rest were profuse. It was decided to decompress the nerve in the facial canal. Six weeks after operation there was still no nerve conduction, but a needle electrode in the levator anguli oris revealed discrete motor-unit activity and highly polyphasic " recovery " potentials on volition. After a further six weeks, discrete motor-unit activity on volition was detected in two more muscles—frontalis and orbicularis oculi—and nerve conduction to frontalis had returned.

Case 15.—A carpenter in a flour mill, aged 71, complained that he had cut his fingers at work without noticing it.

On examination there were sensory loss in the distribution of both median nerves and severe wasting of the lateral half of the thenar eminence in both hands. The patient had noticed this for some years. There was arthritis of both wrists. Diagnosis : carpal-tunnel syndrome (local thenar atrophy).

Muscle-testing.—On stimulation of the median nerve at the wrist there was no response from the thenar muscles supplied by the median nerve, but the lumbrical muscle of the index finger contracted well. (Stimulation of the ulnar nerve at the wrist had proved that this was not a case in which all the lumbricals were supplied by the ulnar.)

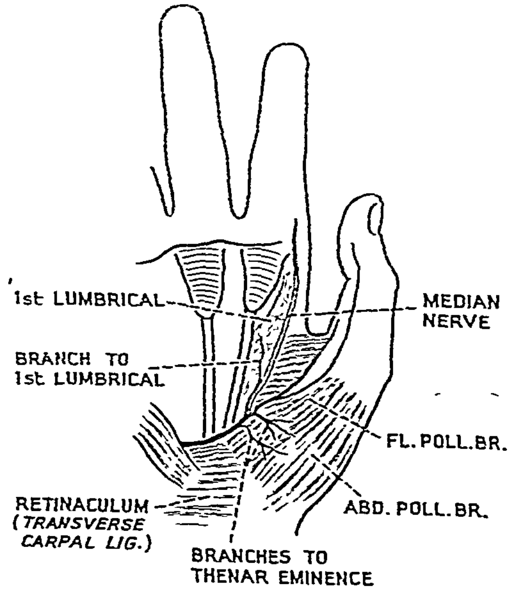

Fig. 10—Innervation of thenar and 1st lumbrical muscles.

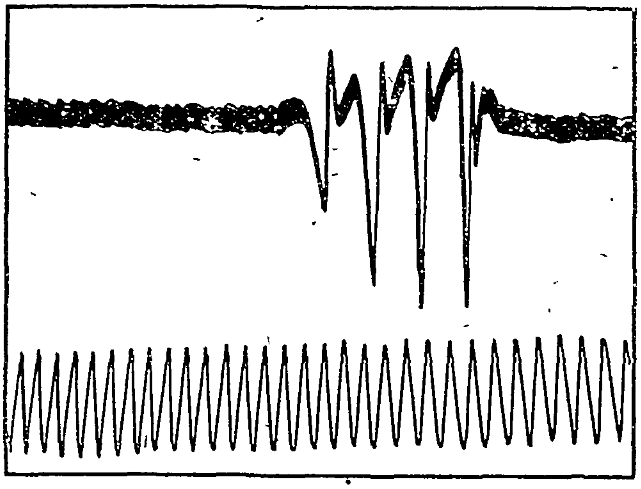

Fig. 8—Group motor-unit potentials, indicating irritation (time: 500 cycles per sec.)

five years he had sometimes felt pain in the neck and round the right shoulder.

On examination there were slight diminution of pain sense in the right little finger, and a similar patch on the right thigh; wasting of all the small muscles of the right hand, especially the 1st dorsal interosseous, with loss of power and poor grip, although the wrist muscles appeared to be normal; left biceps-jerk brisker than the right; other reflexes normal. Radiography showed bilateral cervical ribs and loss of space between the lower cervical vertebræ. Thoracic-outlet syndrome was tentatively diagnosed, although the clinical impression was that ulnar neuritis could not be ruled out.

Electromyography.—Needle electrodes in the right hypothenar eminence revealed discrete motor-unit activity on volition, but no spontaneous activity at rest; in the 1st dorsal interosseous there was spontaneous activity, both fibrillation potentials and rhythmic diphasic potentials; spontaneous diphasic potentials were found in the extensor carpi ulnaris.

Diagnosis: nerve irritation coupled with destruction of some nerve-fibres.

Operation.—Surgical exploration was undertaken; the cervical rib did not seem to be pressing on any nerve structure in its neighbourhood, and it was consequently left intact. Scalenotomy was performed.

Subsequent electromyography some months after operation revealed that spontaneous irritation potentials had disappeared from the right 1st dorsal interosseous and the extensor carpi ulnaris (the muscles in which they had been detected at the previous examination before the operation).

Case 11.—A housewife, aged 66, complained of pain down the outer border of the left arm as far as the thumb for four months, accompanied by pins-and-needles, and weakness of the arm and hand. There had been wasting of the small muscles of both hands for nearly forty years, and a cervical rib had been removed from the right side, with relief of symptoms, in 1911.

On examination there was slight diminution of pain sense on the inner side of the left arm, and some wasting of the thenar muscles of the left hand. There was loss of pain sense in the right thumb, index and middle fingers, and considerable atrophy of the right hand muscles, although the patient did not complain about this hand. The blood-pressure was 195/110 mm. Hg. Radiography showed a left cervical rib.

Muscle-testing.—Intensity-duration curves of the left abductor pollicis brevis, 1st dorsal interosseous and abductor minimi digiti were normal.

Electromyography.—Needle electrodes inserted into the left abductor minimi digiti and thenar muscles showed normal sustained pattern of motor-unit activity on volition and no spontaneous activity.

Diagnosis: no electrical abnormality.

The special interest of these four cases lies in the electromyographic detection of signs of nerve irritation in the first three, and absence of it in the fourth (case 11). Rhythmic diphasic potentials, which produce a characteristic "chugging" sound in the loud-speaker, suggest irritation, and when found in muscles supplied by roots suspected of being subjected to pressure from disc material, &c., may help materially to settle a diagnosis that is in doubt.

In case 8 it was possible to state exactly which nerve-root was affected, owing to the silence in the two muscles supplied by C5 and C6 (biceps and deltoid), and the presence of irritation potentials in two supplied by C6 and C7 (triceps and extensor carpi radialis). It was the more convincing for the subsequent demonstration of the disappearance of signs of irritation. This was a case in which all the necessary information was obtained with surface electrodes only, without using needle electrodes.

Owing to the pronounced psychoneurotic element in case 9 it was considered unwise to make any further electrical examination, especially since the symptoms subsided under treatment; there is little doubt that the irritation potentials detected earlier would have disappeared.

Case 10 was not examined electromyographically for some months after the operation. It was not easy to assess the result clinically, because the patient was going through rather a miserable time, having lost his job, and being in despair about finding another; this circumstance naturally made him most pessimistic about everything, especially his disability. As was to be expected, there was as yet no change in the paræsthesiæ and muscular wasting, and he felt that his scalenotomy had been in vain. In these circumstances it was most fortunate that a second electrical examination showed that pressure on the nerves had been relieved, and that signs of irritation were no longer present. The patient was much encouraged by this report and at his next attendance at the neurological clinic appeared almost jubilant, having secured a better job (which he had at first thought beyond the power of his wasted hand). The pain had abated, and he thought his hand was filling out.

Case 11 was deceptive. The symptoms suggested pressure on the lower portion of the brachial plexus, and the radiogram and previous history of cervical rib seemed to support this assumption. But the electrical examination and report of normal responses were justified by subsequent events; further observation and questioning betrayed the fact that the pain in the patient's arm was brought on by exertion and relieved by rest. This case proved to be one of hypertensive heart-disease with angina of effort.

BRACHIAL PLEXUS

Case 12.—A man, aged 54, had four months' history of weakness and wasting of his right hand and forearm, and six months' history of numbness on the inner side of the arm and forearm. Two years before, he had volunteered to go up on the stage at a variety show and be swung round by a man on roller-skates holding him under the armpits; a month later he had a sudden pain in the right shoulder, radiating down the arm, while he was sitting having his tea. There was no more trouble until he noticed that his hand was beginning to lose power and appeared to be wasting, four months before he came for advice.

On examination were found loss of sensation to pinprick on the inner side of the right arm and forearm but no other sensory change; wasting and weakness of the flexors of the right wrist and all the small muscles of the right hand; the right forearm was 1 in. smaller than the left. The C.S.F. was normal. Radiography showed narrowing of the lower cervical intervertebral foramina by osteophytes. The clinical diagnosis lay between radiculitis and spinal-cord tumour.

Electromyography showed that conduction in the median and ulnar nerves at the wrist was reduced but equal. Electromyography with needle electrodes revealed reduced motor-unit activity on volition in the flexors of the wrist and all the small muscles of the hand; spontaneous fibrillation potentials were present in the flexors of the wrist at rest.

Diagnosis: denervation of the muscles supplied by the lower part of the brachial plexus.

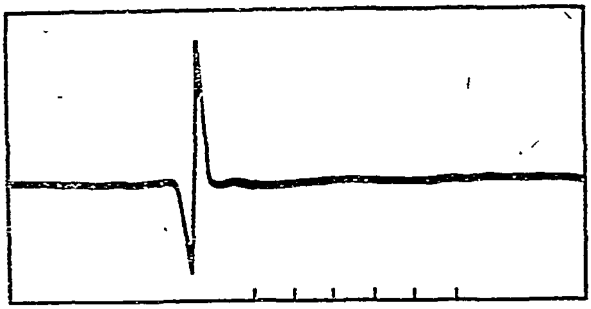

Fig. 12—Short-period potential, as seen in myopathy (scale: millisec.).

Case no.	*Clinical diagnosis*	*Electromyography*	*Conclusion*
1	Atypical progressive muscular atrophy	Synchronisation	Diagnosis confirmed
2	As in case 1	"	"
3	? Friedreich's ataxia ? Poliomyelitis	"	Probably poliomyelitis
4	? Poliomyelitis ? Infective neuritis	"	"
5	Syringomyelia	"	Diagnosis confirmed
6	Lymphatic leukæmia, drop-foot	"	Intramedullary lesion
7	Glioma of cord	No synchronisation "recovery" potentials	Suggestions about pathology
8	Atypical cervical disc lesion	"Irritation"	Lesion localised, postoperative investigation
9	? Osteo-arthritis ? Cervical disc ? Functional	"	Organic lesion diagnosed and treated
10	? Ulnar neuritis ? Cervical rib	"Irritation" and fibrillation	Scalenotomy. postoperative investigation
11	? Cervical rib	No electrical abnormality	Final diagnosis: angina of effort
12	? Radiculitis ? Cord tumour	Fibrillation of hand and flexors of wrist	Suggested combined ætiology of osteo-arthritis and trauma
13	Birth palsy C3–7	Activity in biceps in phase with respiration	Crossed reinnervation from root C4 to musculocutaneous and radial
14	Ramsay Hunt syndrome	No signs of recovery after 3 months	Facial nerve decompressed, recovery
15	Carpal-tunnel syndrome	Fibrillation in thenar muscles, lumbrical of index normal	Suggested mechanism of production of lesion
16	? Lumbar disc ? Lateral popliteal palsy	Fibrillation in tib. ant. and peronei; "recovery" in biceps femoris (short head)	Lateral popliteal injury at level of hip; recovering
17	? Peroneal muscular atrophy	Trains of high-frequency oscillations	Peroneal muscular atrophy with myotonia

CONCLUSION

This list of cases is, of course, far from exhaustive, and is not intended to be a complete representation of disorders in which electromyography is of value. No mention has been made, for instance, of myopathy, in which the mechanical inefficiency, coupled with normal, albeit decreased, electrical reactions but short-period potentials (fig. 12), renders the electromyograph an invaluable means of distinguishing this disorder from those of myelogenic or neurogenic origin; nor has myasthenia gravis been included, although electromyography is now regarded in some countries as an indispensable method of assessing the severity of the disease (rapid fatigue can be measured in this way with a degree of accuracy impossible by clinical methods alone). But the variety of diseases represented will, it is hoped, indicate that electromyography can no longer be regarded as of purely academic interest, with no clinical value.

It has been stated already that the method is still in its infancy. For this reason it is more than ever desirable to correlate the clinical condition with the electrical findings. When patients have been sent for electromyography it would be greatly appreciated if the follow-up scheme could be made to include a note on progress for the electrodiagnostic department concerned; it is only by means of such information that obscure electrical phenomena can be understood and correctly interpreted.

It is a pleasure to acknowledge the help and advice of Dr. Philippe Bauwens, who made the electrical examinations in the department of physical medicine at St. Thomas's Hospital and permitted the use of the photographic tracings, which were prepared by his technical assistant, Mr. Peter Styles.

Ten of the patients were from the West End Hospital for Nervous Diseases, four were from St. Thomas's Hospital, and three from St. Stephen's Hospital, Chelsea. I wish to thank the physicians concerned for their permission to publish the various case-records, especially Dr. C. Worster-Drought, whose encouragement and guidance have been invaluable.

CARDIAC FAILURE *

BASIL THOMAS PARSONS-SMITH
M.D. Lond., F.R.C.P.
CONSULTING PHYSICIAN, NATIONAL HEART HOSPITAL, LONDON

(*Concluded from p. 894*)

Treatment

The rational treatment of patients suffering from heart-failure should take into consideration, whenever possible, the factors responsible for its development and the extent to which these can be removed or controlled.

Reviewing fifty cases I found that in the majority (31) the failure was due to acute intercurrent infections or to the natural progress of various cardiovascular diseases. In the more favourable cases (19), the ætiological factors comprised: overstrain, physical or mental, singly or combined; indulgence, idleness, and intemperate living; severe anæmia; thyrotoxicosis; and pregnancy. Recognition of these factors was of great help alike in treatment, in prognosis, and in rehabilitation.

Within reasonable limits it is usually advisable to mould the programme of treatment—whether medicinal, dietetic, or any other—according to the age, constitution, and personality of the individual. In giving our opinion, followed by our advice, the tone as well as the substance of our statement must be deliberately considered. The sensitive must be treated with kindness; the weak encouraged; the obstinate firmly handled; the careless warned; the disobedient threatened or even alarmed. At times we must appeal to the intellectual, at times to the emotional, side of the patient's mind, in setting before him his condition, his prospects, and his duty. According to the individual, an important factor in his treatment will be to yield at the right time, or on the contrary to decline to compromise, and to make promises—which incidentally are very valuable means of treatment—with great caution.

CONGESTIVE FAILURE

The specific remedies for congestive heart-failure will probably include rest, digitalis, and mercurial diuretics: and. in addition, palliative treatment is usually needed for complicating symptoms. Pain, anxiety, insomnia, faintness, breathlessness, and flatulence may be attended with distress or danger which calls for immediate relief.

There is general agreement nowadays regarding the curative properties of *digitalis* in cardiac failure with congestion. Mackenzie (1911) emphasised its action in failure with auricular fibrillation, and its value in cases

---

* The Lumleian lectures delivered at the Royal College of Physicians on April 11 and 13, 1950.

Electromyography.—Needle electrodes inserted in the thenar muscles revealed denervation by the reduced pattern of motor-unit activity on volition and the presence of spontaneous fibrillation potentials at rest.

Diagnosis confirmed, and escape of 1st lumbrical noted.

Case 16.—A railway coachmaker, aged 48, stated that he was perfectly fit until Jan. 25, 1949, when, while kneeling to fix a railway-carriage seat in position, bending forward, lifting and pulling, he suddenly felt a shooting pain in the right lower lumbar region; this was followed by aching pain in this region for a month. Next he got cramp in his right toes, and the foot felt numb, and he could not use his right foot properly. It had remained weak ever since, but the pain had gone. There had not been any sciatic pain at any time.

On examination nine months after the original complaint, the patient had a complete lower motor-neurone paralysis of all the muscles supplied by the lateral popliteal nerve, but no other signs, either motor or sensory.

Muscle-testing revealed denervation of the right anterior-compartment muscles and peronei.

Electromyography.—Needle electrodes inserted into these muscles revealed grossly diminished motor-unit activity on volition, with spontaneous fibrillation potentials at rest; and in the short head of the biceps femoris decreased motor-unit activity on volition, with polyphasic complex "recovery" potentials. The long head of the biceps femoris showed a normal sustained pattern of motor-unit activity on volition, and no spontaneous activity at rest.

These three cases of peripheral nerve lesion were of different ætiology, case 14 being due to infection combined with pressure, case 15 to a pressure lesion possibly aggravated by arthritic swelling of the carpal joint, and case 16 probably to a traction injury.

The Ramsay Hunt syndrome, of which case 14 was typical, is almost certainly due to infection of the geniculate ganglion with the zoster virus, but the inflammatory swelling spreads distally in the nerve, with the result that there is often compression in the narrow facial canal. The electromyograph was instrumental in showing that in this case no recovery was to be hoped for without surgical interference; the subsequent electrical examinations proved that treatment had been successful, long before it was possible to determine any clinical improvement.

The point of interest in case 15 lies in the anomalous response to stimulation of the median nerve at the wrist. If, as is generally supposed, the carpal-tunnel syndrome were due to compression of the entire median nerve in the carpal tunnel between the carpus and the retinaculum, one might expect the two radial lumbricals to be involved as well as the thenar muscles. The lumbricals often escape, however, even in cases in which the usual preliminary testing of the median and ulnar nerves at the wrist has shown clearly that these muscles are supplied by the median nerve. The anatomy of this region seems to explain the electrical findings. The branches of the median nerve to the abductor and flexor pollicis brevis hook over the sharp distal edge of the retinaculum close to its attachment to the ridge of the trapezium, and run back to reach these muscles, while the branch to the lumbricals pursues a straight and untrammelled course distally; the branch to the opponens usually pierces the retinaculum between its attachments to the ridge on the trapezium and the tuberosity on the scaphoid, where it may be subjected to pressure or squeezing (fig. 10). It is perhaps not unreasonable to suppose that the syndrome is caused not only by the narrowing of the tunnel which follows fracture or severe arthritis but also to a considerable extent by the sawing effect of the distal edge of the retinaculum. This is a case in which electrical investigation draws attention to the mechanism of production of a well-known syndrome that would be very difficult to establish from clinical examination alone.

Case 16 was at first justifiably suspected of being an example of prolapsed intervertebral disc, but the final distribution of the motor paralysis suggested a lateral popliteal lesion; this was difficult to reconcile with the history of pain in the lower portion of the back. The sciatic nerve often divides into its two terminal branches (medial and lateral popliteal) as high up as the sacral plexus, and when it does so the lateral popliteal invariably pierces the piriformis muscle (the larger medial branch passing under this muscle as usual). In this position the lateral popliteal branch is much more vulnerable, especially when the patient is in a squatting posture. If it were torn by stretching while gripped in the substance of the piriformis, pain in the lumbar region would naturally result, as well as motor paralysis. This is possibly what happened in the case here described. It is usually considered that lateral popliteal palsy is caused by compression against the head of the fibula; but by electromyography it is possible to show that the short head of the biceps (the only muscle in the thigh innervated by the lateral popliteal) is sometimes denervated in these cases, and in such instances the point at which the nerve is damaged must lie above the knee; the point of exit from the pelvis seems the most likely place.

MUSCLES

Case 17.—A cornchandler, aged 71, complained that his legs were wasting; his hands had been wasted for thirty years. He was married but had no children. A brother was afflicted with similar muscle wasting.

On examination the patient was bald and with poor vision, but no lens opacities were discernible on ophthalmoscopy. There was wasting of all the small muscles of both hands and of the anterior-compartment muscles and peronei of both legs, with bilateral pes cavus. Peroneal muscular atrophy was diagnosed. Reactive myotonia was present in the brachioradialis and extensors of wrists on both sides, but no active myotonia.

Electromyography.—Needle electrodes in the left thenar eminence, left extensor digitorum communis, and right and left peronei, revealed decreased motor-unit activity in all these muscles; there were spontaneous fibrillation potentials at rest in all but the peronei and trains of high-frequency oscillations (fig. 11) ("dive-bomber" sounds) in all muscles tested. These spontaneous high-frequency discharges are characteristic of myotonia. Their origin is obscure.

Diagnosis: peroneal muscular atrophy with myotonia.

Case 17 presented the usual features of peroneal muscular atrophy, although the involvement of the legs at such a late age is somewhat uncommon; there were no obvious sensory changes; dystrophia myotonica was a possible diagnosis, but there was no active myotonia detectable clinically, but only reactive myotonia in the muscles specified. Moreover, there was no pronounced wasting of those muscles most often and prominently wasted in dystrophia myotonica—i.e., sternomastoids, muscles of mastication, and facial muscles. The high-frequency oscillations detected in the loud-speaker on insertion of the needle electrodes into the muscles demonstrated myotonia which, being purely reactive, would clearly be overlooked on clinical examination.

SUMMARY OF CASES

To sum up, the 17 neurological cases which have been presented to illustrate the uses of electromyography may be tabulated as follows.

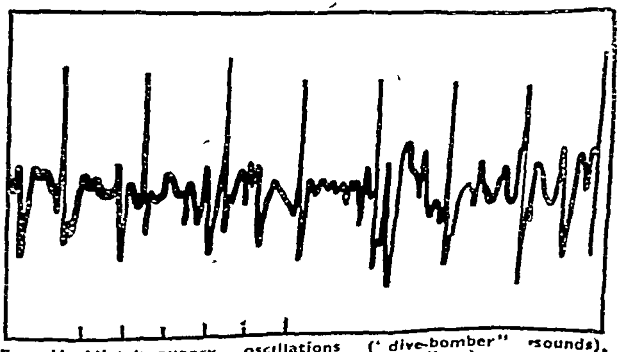

Fig. 11—High-frequency oscillations ("dive-bomber" sounds), suggesting myotonia (scale: 10 millisec.).

are essential items of the diet, which includes specified amounts of various ordinary foods (all without added salt). The fluid intake is limited to about 50 oz. daily in uncomplicated cases, an increase being indicated if the blood-urea is high or rising.

Hayward (1949) states that, in cases complicated by renal dysfunction, fever, or excessive perspiration, a low-sodium diet may precipitate symptoms of salt depletion including muscle cramps, colic, nausea, and vomiting, with a rising blood-urea, and he refers to four deaths attributed to this cause by Soloff and Zatuchni (1949).

In patients with long-standing heart-failure—particularly those with tricuspid incompetence and hepatic congestion—hypoproteinæmia may be responsible for œdema. Here a *high-protein diet* may restore a normal or an approachingly normal level of plasma-proteins, and the patients may then respond to diuretic medication.

Intractable œdema and serous effusions may need *mechanical drainage*: Bedford (1949) advises that if a hydrothorax fails to clear in 1–2 weeks it should be aspirated, since long-continued pulmonary collapse may lead to secondary changes such as brown induration, pleural thickening, or even atelectatic bronchiectasis.

As an extrarenal method of depleting the body sodium Leiter (1948) has suggested *peritoneal dialysis* with 5% glucose. He recorded one case of massive œdema in which, all the conventional remedies having failed, he carried out continuous peritoneal irrigation with 5% glucose at the rate of 500 ml. per hour for 6 days. The œdema cleared rapidly: the fluid draining from the peritoneal cavity contained 312–331 mg. sodium per 100 ml.

For patients with congestive heart-failure whose compensation remains impaired after a long course of medicinal remedies, *therapeutic myxœdema* should be considered.

Total thyroidectomy in the treatment of congestive heart-failure and ischæmic heart-disease was introduced by Blumgart and his colleagues (1933), who thought that it would lower the oxygen-consumption of the body, and consequently the output and work of the heart. Blumgart et al. (1935) reported on fifty patients, aged 18–69, of whom twenty-four recovered and were able to work 2–18 months after the operation and six regained compensation after recurrences of heart-failure; there were six operative deaths, and six subsequent deaths, two patients were unrelieved, and at the time of the report it was too early to decide on the effect the remaining six patients.

In the experience of my colleague Evan Bedford (1949) the value of induced myxœdema in certain types of anginal and congestive heart-failure has been amply confirmed. He stresses its controlling action on the circulatory mechanism, but also the complications—including anæmia, fluid retention, and mental dysfunction—for which it may be responsible.

The selection of suitable cases for therapeutic myxœdema is admittedly difficult. It is contra-indicated in patients with uncontrollable œdema, in those with rapidly progressive disease, and in those whose range of circulation is greatly reduced by high-grade mitral or aortic stenosis. Bedford believes that total thyroidectomy is a more certain and probably a safer method of producing and maintaining myxœdema than is thiouracil, and that it is the preferable remedy for those patients whose general condition admits of operation. He suggests that therapeutic myxœdema is indicated in:

1. Chronic left heart-failure without appreciable systemic œdema (especially where there is paroxysmal dyspnœa and anginal pain).
2. Auricular fibrillation or flutter in which digitalis fails to control the average ventricular rate.
3. Chronic right heart-failure which can be kept more or less dry by mercurial diuretics when the patient is at rest but which persistently recurs when he is ambulant.

As an alternative to thyroidectomy, Sharpey-Schafer (1946) tried long-term thiouracil treatment in twelve cases of severe cardiac failure, seven of the low-output and five of the high-output type. He estimated the cardiac output and the right auricular pressure by cardiac catheterisation, and he calculated the work of the heart from the product of the cardiac output and the blood-pressure. Thiouracil reduced the basal and the resting oxygen consumption; but, as the arteriovenous oxygen difference sometimes decreased with the fall in oxygen consumption and the blood-pressure was sometimes unchanged, he was of opinion that the cardiac output and the work of the heart might be unaffected by thiouracil. He noted, however, that, as judged by a fall in venous pressure and an improved exercise tolerance, definite improvement occurred in the majority of the cases in both the tests.

Bedford (1949) reported thirty-five cases of failure treated by thiouracil, the results being good and worth while in about half and slight in about a quarter. Agranulocytosis developed in three of the patients, of whom one died and two recovered, both later undergoing total thyroidectomy.

ANGINAL PAIN

The treatment of patients in whom anginal pain is the dominant symptom of coronary atheroma must include both precautionary measures and symptomatic remedies. It is fundamentally important that patients shall personally assess their pain threshold, below which they must endeavour to plan their routine of life and habits; also that they shall be encouraged to take easy forms of exercise according to their tolerance and to reduce their weight if this is deemed to be excessive.

Apart from nitrites, the medicinal treatment of angina pectoris secondary to coronary atheroma is singularly disappointing. Many drugs have been recommended, and, though certain xanthine preparations appear to be helpful at times, the results have otherwise been insufficiently convincing. Mild sedatives are indicated for the obviously nervous and excitable patients, the frequency and severity of whose attacks may be further controlled by occasional courses of short-wave diathermy. In severe cases it may be desirable to prescribe a long period of complete rest with a rigidly restricted diet and light general massage, adequate sedation being maintained in order that patients shall have the maximum of relaxation, both mental and physical.

The value of thiouracil in intractable cases has been under consideration recently. Hollander and Mandelbaum (1948) treated ten patients, whose histories ranged from 5 months to 7 years, the dosage of 6-propylthiouracil being increased gradually from 50 to 200 mg. daily. In four the substernal pain was relieved after 8 weeks' treatment, the basal metabolic rates, though lowered in three, remaining within normal limits. One case with a basal metabolic rate of − 8% became free from anginal attacks when the level fell to − 26%, and three with raised initial levels improved while their rate was still above normal limits. Seven patients developed breathlessness and œdema of the legs owing to water retention, but toxic effects on the blood were excluded in all these cases. The investigators noted that, to obtain relief of anginal pain, the basal metabolic rate need not be lowered to myxœdema levels.

Two surgical remedies—total thyroidectomy and paravertebral sympathetic block—are available for carefully selected patients whose condition is little, if at all, relieved by medical remedies and whose painful seizures are so frequent and severe as to disable them almost completely.

Paravertebral sympathetic block, first practised by Mandl (1925) and Swetlow (1926), is now recognised as a safe and successful means of relieving intractable anginal with regular rhythm was subsequently recognised (Janeway 1913, Christian 1922, Luten 1924, Marvin 1927, Gavey and Parkinson 1939, Paul Wood 1940).

Gavey and Parkinson (1939) investigated a group of patients in whom failure with normal rhythm was secondary to various conditions including hypertension, rheumatic valvular disease, and syphilitic heart-disease. They regarded breathlessness, liver enlargement, and œdema (with or without hydrothorax) as the criteria of failure, and they considered that relief in these respects, in conjunction with adequate diuresis, was satisfactory evidence of improvement under treatment. Their general conclusions were:

1. In heart-failure with normal rhythm, digitalis is helpful in rather more than half the cases.
2. The heart-rate in failure with normal rhythm is, as a rule, moderate (the average rate in their series before digitalis was 85).
3. Whatever the initial rate, digitalis often reduces it; but a reduction in heart-rate is not always accompanied by clinical improvement.
4. Good clinical results may be obtained without any reduction in rate.

Paul Wood (1940) investigated twenty cases of congestive heart-failure with normal rhythm, including twelve cases of hypertensive heart-disease, three of chronic cor pulmonale, one of mitral stenosis, one of ischæmic heart-disease, and three with unknown ætiology. Eighteen of the cases (fourteen with right, and four with left, ventricular failure) responded to digitalis; improvement in right failure was judged by a decline in the venous pressure, and in left failure by significant lowering of the arm-to-tongue circulation-time. In all but three of the long-period studies the pulse-rate fell with digitalis, on an average from 98 to 85 per minute; but observation showed that the fall in venous pressure following intravenous digoxin was not due to slowing of the heart.

The accepted opinion nowadays is that the value of digitalis therapy differs in the different forms of heart-failure. Striking benefit is obtained in right-sided failure, in isolated failure of the left ventricle with pulmonary engorgement, in hypertensive failure, and in the treatment of certain arrhythmias, notably auricular fibrillation and auricular flutter.

Though digitalis appears to be beneficial in those cases of emphysema heart-failure which are complicated by auricular fibrillation, Howarth and her colleagues (1947) have shown that it is otherwise contra-indicated in this condition. They noted that emphysema cases with a normal blood-pressure differ from cases of low-output failure in that their resting output is increased: when the venous filling pressure is reduced by digitalis or by venesection the cardiac output usually falls. Other conditions in which digitalis is contra-indicated include the heart-failure which occurs in shock, in thyrotoxicosis, in severe anæmia, and in the acute stages of carditis.

Apart from thyrotoxicosis cases, the heart-failure of auricular fibrillation is usually *well controlled by digitalis*, the dosage being so regulated that the average ventricular rate is maintained reasonably near the normal. For those patients, however, who are persistently heart-conscious and materially incapacitated in spite of full digitalisation, an attempt should be made to restore the normal rhythm with *quinidine*. This drug is not infallible; but, so long as the patient is not suffering from acute carditis or severe cardiac failure, and has no history of embolic accidents, it can be used with reasonable confidence. Success is most likely when the fibrillation is of recent origin, in cases in which it has followed acute infections, and in thyrotoxic patients in whom normal rhythm does not return after thyroidectomy.

Though sometimes permanent, the quinidine cure of auricular fibrillation may be of limited duration. Further courses may be indicated if the fibrillation recurs, and as a rule the patient will again respond to the same dosage. In successful cases a short period of complete rest, followed by a quietly organised convalescence, will usually suffice to consolidate the cure, and the quinidine medication may cease entirely, its subsequent value in prophylactic dosage being negligible.

Recent investigations by Howarth and her colleagues (1946, 1947) have confirmed the value of two other remedies in heart-failure of the congestive type—namely, venesection and theophylline. It was observed that in cases of low-output failure intravenous injections of *theophylline* reduced the venous filling pressure and increased the cardiac output, and that they did this more rapidly than intravenous digoxin. It was suggested that, as the effect of theophylline on the right auricular pressure may not be maintained, digoxin and theophylline should sometimes be prescribed in close succession, to secure summation of their actions. In all the cases of low-output failure with right auricular pressure above the sternal angle, *venesection* induced a fall in the venous filling pressure and a rise in the cardiac output, and usually there was a fall of blood-pressure. Though closely similar results were obtained with venesection and with digitalis, the former usually lowered the blood-pressure, whereas with the latter the blood-pressure was maintained and often raised. Comparing the value of the two remedies Howarth et al. suggested that the chief difference was in the long-term effects; whereas after venesection the right-auricular pressure tends to rise again, digitalis often maintains the filling pressure of the heart at a lower and better level for an indefinite period.

In congestive heart-failure the retention of sodium is known to promote peripheral œdema and transudation into the serous cavities. For these conditions we can combine two reliable remedies, mercurial diuretics and a low-sodium diet. *Mercurial diuretics* induce excretion of large quantities of water and sodium chloride, and —except in cases of renal dysfunction, where they are contra-indicated—their curative value has been amply confirmed. Particularly effective in right heart-failure with systemic venous engorgement and peripheral œdema, mercurials are also useful in gross pulmonary venous congestion secondary to failure of the left ventricle.

Following the pioneer work of Karell (1866), Schemm (1942), Kempner (1946), and others, a *restricted intake of salt* is now regarded as an essential item in the management of patients with congestive heart-failure, in addition to which a diet suitably low in calories is prescribed to reduce metabolism and decrease the work of the heart.

Opinions differ on the composition of a safe and reasonably palatable low-sodium diet. The basis of the Karell milk cure is a severe limitation of fluid, together with a low-calorie diet and a restricted intake of sodium (0·4 g. per day). Though temporarily valuable in the preliminary treatment of well-nourished patients and those with hypertensive failure, the Karell diet is *regarded as excessively rigorous for congestive failure* of average severity. The Kempner rice diet, valued at 2000 calories, consists of rice, fruit juices, sugar, and 0·2 g. of sodium, together with vitamins and ferrous sulphate. This diet is unpalatable, monotonous, and difficult to arrange, and the consensus of opinion is this country is that patients respond favourably to a mixed diet of approximately 2000 calories containing 0·5 to 1·0 g. of sodium.

I am indebted to Dr. Shirley Smith (1950) for particulars of the low-sodium dietary régime he has formulated for patients with congestive failure and a tendency to fluid retention. He recommends modified diets of slightly varied composition, the average value of which is 1816 calories, and the average *sodium content 0·529 g.* Measured quantities *of low-salt bread and salt-free* butter

Harken and his colleagues prefer the creation of an atrial shunt for those patients whose cardiac output is within normal limits, and, if the condition is complicated by uncontrolled tachycardia or anginal pain, they recommend cardiac denervation.

Swan (1949) suggested the creation of a pulmonocaval venous shunt by the anastomosis of a proximal segment of the azygos with the right inferior pulmonary vein. Bland and Sweet (1949) performed this operation in five cases of advanced mitral stenosis in which pulmonary venous hypertension caused recurring attacks of pulmonary œdema and hæmoptysis. In three of the cases it was very successful; in another (operated on recently) the early progress was satisfactory. In no case was there any clinical evidence that reduction in the left auricular pressure impaired the peripheral circulation. Bland and Sweet regarded the operation as a compromise, not as a cure, suitable patients being those with small strong hearts and a tendency to circulatory complications in the lungs.

Cossio and Perianes (1949) advocate two surgical remedies—tricuspid valvulotomy and ligation of the inferior vena cava below the renal veins—for the relief of the "cardiac lung" in those cases of left ventricular failure and mitral stenosis which can no longer be managed successfully by medical treatment. They performed tricuspid valvulotomy under local anæsthesia on four patients. The first was a man suffering from syphilitic aortitis and severe heart-failure, and his postoperative progress was entirely satisfactory: his urgent symptoms were rapidly relieved and a material decrease of pulmonary congestion was confirmed by radioscopy. Progress was well maintained, and six months later, apart from slight breathlessness with fast walking, he was relatively symptom-free. Of the three other patients, two were definitely improved. One survived 5 months; the other died from a pulmonary infarct $2^1/_2$ months after the operation. The third patient died in collapse within 8 hours of the operation, during which a paroxysm of tachycardia precipitated the development of acute pulmonary œdema; the tricuspid valve was extensively sectioned, the intraventricular pressure fell to 32 mm. Hg, and dyspnœa and tracheal stridor disappeared rapidly, but tachycardia persisted and terminated fatally.

Ligation of the inferior vena cava was performed in an unspecified number of cases with one operative death and good results in the remainder. Pulmonary engorgement was rapidly relieved in the successful cases and breathlessness disappeared or decreased to the extent that the patients were comfortable in the recumbent position.

In Cossio's opinion, tricuspid valvulotomy and ligation of the inferior vena cava are relatively simple and well-tolerated operations, both procedures reducing the right ventricular output, decreasing the pulmonary congestion, and improving the efficiency of the left ventricle.

After his visit to Cossio's clinic in Buenos Aires, Heim de Balsac verified the value of ligaturing the inferior vena cava below the renal veins in cases of mitral stenosis and also in cases of left ventricular failure, the aim of the operation being to decongest the lungs by reducing the stroke-output of the right ventricle. It is suggested that patients suitable for this form of treatment are those whose condition, in spite of all the usual medical remedies, is aggravated by persistent pulmonary engorgement and by such developments as infarction and œdema.

I am indebted to Heim de Balsac for a personal communication in which he summarises the indications for, and the results which can be achieved by, ligature of the inferior vena cava in carefully selected cases of cardiopulmonary disease. In thirty-three of a group of forty cases the operation was eminently successful both objectively and subjectively. Breathlessness, cough, and expectoration were rapidly relieved; there was a gradual fall in the auricular and the arterial blood-pressures, slowing of the heart-rate, and a general improvement in the circulatory compensation. The radiological findings were impressive; the cardiopulmonary haziness underwent gradual resolution, both lungs presenting a normal transparence within 1–2 weeks after the operation, and there was at the same time a significant diminution in the size of the cardiac silhouette.

We may fairly assume that the brilliant achievements of surgeons in this country, in France, and in America, have considerably widened the scope of treatment available for cardiac patients. The successes recorded to date amply justify operation in some varieties of cardiac disease which medical treatment fails to control. At many points cardiac surgery has now emerged from the experimental stage, and with coöperation between surgeons and physicians, an increasingly optimistic outlook will be permissible for patients who suffer from certain grave types of disease of the heart.

pain. It is devised to block, by means of alcohol injections, the sensory pathways proceeding from the heart, which converge and unite in the upper five thoracic sympathetic ganglia.

White (1935) recorded his results with paravertebral block in thirty-five cases of severe angina: twenty-four were 90–100% relieved, eight were improved, and three were failures. Braun (1946) studied the effect of paravertebral block on the electrocardiogram. The treatment consisted in four to seven injections at intervals of 3–6 days, procaine being used for the first injection, and procaine and alcohol for the others. In eight of his twelve cases the terminal deflections of the cardiograms showed improvement, and this he tentatively attributed to an increase in coronary blood-flow and a greater supply of oxygen to the myocardium: it might be the direct sequel to the sympathetic block or of relief of reflex spasm in unaffected vessels when pain was abolished.

CORONARY THROMBOSIS

The management of patients with acute coronary thrombosis is often difficult because of shock, which may be transitory but may be extremely grave.

The clinical features of shock are expressive of circulatory failure, which is due primarily to diminished cardiac output, usually complicated by widespread vasoconstriction. The symptom-complex is characteristic. The patient lies flat, sensation being as a rule dulled, but restlessness and excitement are not uncommon. The skin is pale, cold, and clammy; there is profuse perspiration; the mucous membranes and the extremities are cyanotic, and the features are sunken. The pulse is usually rapid, small, and at times impalpable. The heart-sounds are approximated, dull, and at times inaudible. There may be triple rhythm. In most cases the blood-pressure is lowered in proportion to the degree and the urgency of the shock. Respiration is rapid and shallow, the breath-sounds are feeble, and moist râles can usually be heard at the lung bases. Collapsed veins and a lowered venous pressure are confirmatory of the peripheral circulatory failure which characterises the initial stages of cardiac shock following coronary occlusion.

In elderly patients, and in those with pre-existing cardiovascular lesions, acute myocardial infarction is often accompanied by pulmonary and systemic venous engorgement.

The orthodox treatment of coronary thrombosis includes complete rest, morphine in dosage sufficient to relieve the pain, oxygen inhalations, a low-calorie fluid diet, and the reassuring inspiration of expert and sympathetic nurses. When there is shock, measures must be taken to ensure the patient's warmth and freedom from exposure, and oxygen should be administered freely (preferably through a nasal catheter or a B.L.B. mask) to control cyanosis, dyspnœa, and restlessness. Various drugs, including nikethamide, caffeine, and ephedrine have been recommended for counteracting hypotension, and Fishberg (1940) has emphasised the value of adrenaline in patients apparently succumbing to the shock of coronary thrombosis whose pulse is impalpable and whose blood-pressure is unobtainable. When drugs fail to restore an effective head of blood-pressure, it may be worth giving small intravenous infusions (250–500 ml.) of physiological saline, the drip being arranged at 5 ml. per minute. This form of treatment is obviously contra-indicated in elderly patients with a previous or recent history of congestive heart-failure, but in suitable cases its curative value may be dramatic. As a rule its efficacy can be judged by estimates of the venous and the arterial pressures, and by frequent tests for signs of threatened pulmonary œdema, together with assessment of the patients' general reaction.

The use of anticoagulant drugs is now considered important as a means of preventing the various thrombo-embolic accidents to which patients are liable during the convalescent stages of their illness. Wright and his associates (1948) analysed the records of 800 cases of coronary thrombosis, 368 treated conventionally, and 432 treated also with anticoagulants (heparin and dicoumarol). Thrombo-embolic complications occurred in 25% of the controls and in 11% of the treated cases, the mortality-rate being 24% in the controls as opposed to 15% in the group treated with anticoagulants. From a study of seventy-one cases of coronary thrombosis associated with myocardial infarction, McCall (1948) concluded that dicoumarol is a safe and valuable preventive of thrombo-embolic accidents. Daily estimations of the prothrombin-time were, he thought, essential for safe therapy, and hæmorrhagic complications were in his experience readily controlled with menadione bisulphite.

Cardiac Surgery

It remains to mention certain surgical measures which have been devised in recent years, some with a view to diverting the blood-stream in heart-failure cases from severely congested areas, others for the instrumental widening of valvular orifices. Several operations to improve the circulatory mechanics in mitral stenosis have been proposed.

In 1923 Cutler performed valvulotomy on five cases of mitral stenosis; the first patient made a good recovery from the operation, improved considerably for a time, and died 4½ years later. The other four cases all died shortly after the operation.

In 1925 Souttar performed a finger dilatation of the mitral valve on a patient who had suffered from frequently recurring attacks of congestive heart-failure secondary to long-standing mitral stenosis with regurgitation. The girl made an uncomplicated recovery from the operation, and her report three months later was that she felt perfectly well though still somewhat breathless on exertion.

Brock (1950) has performed valvulotomy on seven patients with mitral stenosis, ranging in age from 22 to 42. All except one were suffering from severe degrees of decompensation, three had recurring attacks of congestive heart-failure, and five had had attacks of pulmonary œdema. Two of the patients died, but five made good recoveries and later reported that they were in regular employment, whereas previously they had been almost completely disabled.

Harken and his colleagues (1948) have described two direct-approach operations—valvuloplasty and fenestration of the interauricular septum—which they have performed in selected cases of mitral stenosis. In broad principle, the objects of valvuloplasty are to increase the size of the mitral orifice by wedge resections of the commissures which fuse with and immobilise the valve leaflets, and to restore such a degree of valvular action as will to some extent control the regurgitant stream. Of the two cases reported by Harken et al., in the first the operation was unsuccessful: there was a postoperative rise, rather than a fall, in the left auricular pressure; pulmonary œdema developed, and the patient died in 24 hours. In this case death was attributed to a rise in the pulmonary blood-pressure primarily due to tachycardia, partly also to increased pulmonary filling from the undamaged right ventricle, and partly to increased regurgitation from the left ventricle. In the second case the clinical indications included a low cardiac output and a diminished stroke-volume on exertion, and it was thought that valvuloplasty would increase the range of cardiac compensation. The operation was successfully performed, the patient made an uncomplicated recovery, and his subsequent improvement was regarded as dramatic.

Harken and his colleagues prefer the creation of an atrial shunt for those patients whose cardiac output is within normal limits, and, if the condition is complicated by uncontrolled tachycardia or anginal pain, they recommend cardiac denervation.

Swan (1949) suggested the creation of a pulmonocaval venous shunt by the anastomosis of a proximal segment of the azygos with the right inferior pulmonary vein. Bland and Sweet (1949) performed this operation in five cases of advanced mitral stenosis in which pulmonary venous hypertension caused recurring attacks of pulmonary œdema and hæmoptysis. In three of the cases it was very successful; in another (operated on recently) the early progress was satisfactory. In no case was there any clinical evidence that reduction in the left auricular pressure impaired the peripheral circulation. Bland and Sweet regarded the operation as a compromise, not as a cure, suitable patients being those with small strong hearts and a tendency to circulatory complications in the lungs.

Cossio and Perianes (1949) advocate two surgical remedies—tricuspid valvulotomy and ligation of the inferior vena cava below the renal veins—for the relief of the "cardiac lung" in those cases of left ventricular failure and mitral stenosis which can no longer be managed successfully by medical treatment. They performed tricuspid valvulotomy under local anæsthesia on four patients. The first was a man suffering from syphilitic aortitis and severe heart-failure, and his postoperative progress was entirely satisfactory; his urgent symptoms were rapidly relieved and a material decrease of pulmonary congestion was confirmed by radioscopy. Progress was well maintained, and six months later, apart from slight breathlessness with fast walking, he was relatively symptom-free. Of the three other patients, two were definitely improved. One survived 5 months; the other died from a pulmonary infarct $2^1/_2$ months after the operation. The third patient died in collapse within 8 hours of the operation, during which a paroxysm of tachycardia precipitated the development of acute pulmonary œdema; the tricuspid valve was extensively sectioned, the intraventricular pressure fell to 32 mm. Hg, and dyspnœa and tracheal stridor disappeared rapidly, but tachycardia persisted and terminated fatally.

Ligation of the inferior vena cava was performed in an unspecified number of cases with one operative death and good results in the remainder. Pulmonary engorgement was rapidly relieved in the successful cases and breathlessness disappeared or decreased to the extent that the patients were comfortable in the recumbent position.

In Cossio's opinion, tricuspid valvulotomy and ligation of the inferior vena cava are relatively simple and well-tolerated operations, both procedures reducing the right ventricular output, decreasing the pulmonary congestion, and improving the efficiency of the left ventricle.

After his visit to Cossio's clinic in Buenos Aires, Heim de Balsac verified the value of ligaturing the inferior vena cava below the renal veins in cases of mitral stenosis and also in cases of left ventricular failure, the aim of the operation being to decongest the lungs by reducing the stroke-output of the right ventricle. It is suggested that patients suitable for this form of treatment are those whose condition, in spite of all the usual medical remedies, is aggravated by persistent pulmonary engorgement and by such developments as infarction and œdema.

I am indebted to Heim de Balsac for a personal communication in which he summarises the indications for, and the results which can be achieved by, ligature of the inferior vena cava in carefully selected cases of cardiopulmonary disease. In thirty-three of a group of forty cases the operation was eminently successful both objectively and subjectively. Breathlessness, cough, and expectoration were rapidly relieved; there was a gradual fall in the auricular and the arterial blood-pressures, slowing of the heart-rate, and a general improvement in the circulatory compensation. The radiological findings were impressive; the cardiopulmonary haziness underwent gradual resolution, both lungs presenting a normal transparence within 1–2 weeks after the operation, and there was at the same time a significant diminution in the size of the cardiac silhouette.

We may fairly assume that the brilliant achievements of surgeons in this country, in France, and in America, have considerably widened the scope of treatment available for cardiac patients. The successes recorded to date amply justify operation in some varieties of cardiac disease which medical treatment fails to control. At many points cardiac surgery has now emerged from the experimental stage, and with coöperation between surgeons and physicians, an increasingly optimistic outlook will be permissible for patients who suffer from certain grave types of disease of the heart.

pain. It is devised to block, by means of alcohol injections, the sensory pathways proceeding from the heart, which converge and unite in the upper five thoracic sympathetic ganglia.

White (1935) recorded his results with paravertebral block in thirty-five cases of severe angina: twenty-four were 90–100% relieved, eight were improved, and three were failures. Braun (1946) studied the effect of paravertebral block on the electrocardiogram. The treatment consisted in four to seven injections at intervals of 3–6 days, procaine being used for the first injection, and procaine and alcohol for the others. In eight of his twelve cases the terminal deflections of the cardiograms showed improvement, and this he tentatively attributed to an increase in coronary blood-flow and a greater supply of oxygen to the myocardium: it might be the direct sequel to the sympathetic block or of relief of reflex spasm in unaffected vessels when pain was abolished.

CORONARY THROMBOSIS

The management of patients with acute coronary thrombosis is often difficult because of shock, which may be transitory but may be extremely grave.

The clinical features of shock are expressive of circulatory failure, which is due primarily to diminished cardiac output, usually complicated by widespread vasoconstriction. The symptom-complex is characteristic. The patient lies flat, sensation being as a rule dulled, but restlessness and excitement are not uncommon. The skin is pale, cold, and clammy; there is profuse perspiration; the mucous membranes and the extremities are cyanotic, and the features are sunken. The pulse is usually rapid, small, and at times impalpable. The heart-sounds are approximated, dull, and at times inaudible. There may be triple rhythm. In most cases the blood-pressure is lowered in proportion to the degree and the urgency of the shock. Respiration is rapid and shallow, the breath-sounds are feeble, and moist râles can usually be heard at the lung bases. Collapsed veins and a lowered venous pressure are confirmatory of the peripheral circulatory failure which characterises the initial stages of cardiac shock following coronary occlusion.

In elderly patients, and in those with pre-existing cardiovascular lesions, acute myocardial infarction is often accompanied by pulmonary and systemic venous engorgement.

The orthodox treatment of coronary thrombosis includes complete rest, morphine in dosage sufficient to relieve the pain, oxygen inhalations, a low-calorie fluid diet, and the reassuring inspiration of expert and sympathetic nurses. When there is shock, measures must be taken to ensure the patient's warmth and freedom from exposure, and oxygen should be administered freely (preferably through a nasal catheter or a B.L.B. mask) to control cyanosis, dyspnœa, and restlessness. Various drugs, including nikethamide, caffeine, and ephedrine have been recommended for counteracting hypotension, and Fishberg (1940) has emphasised the value of adrenaline in patients apparently succumbing to the shock of coronary thrombosis whose pulse is impalpable and whose blood-pressure is unobtainable. When drugs fail to restore an effective head of blood-pressure, it may be worth giving small intravenous infusions (250–500 ml.) of physiological saline, the drip being arranged at 5 ml. per minute. This form of treatment is obviously contra-indicated in elderly patients with a previous or recent history of congestive heart-failure, but in suitable cases its curative value may be dramatic. As a rule its efficacy can be judged by estimates of the venous and the arterial pressures, and by frequent tests for signs of threatened pulmonary œdema, together with assessment of the patients' general reaction.

The use of anticoagulant drugs is now considered important as a means of preventing the various thrombo-embolic accidents to which patients are liable during the convalescent stages of their illness. Wright and his associates (1948) analysed the records of 800 cases of coronary thrombosis, 368 treated conventionally, and 432 treated also with anticoagulants (heparin and dicoumarol). Thrombo-embolic complications occurred in 25% of the controls and in 11% of the treated cases, the mortality-rate being 24% in the controls as opposed to 15% in the group treated with anticoagulants. From a study of seventy-one cases of coronary thrombosis associated with myocardial infarction, McCall (1948) concluded that dicoumarol is a safe and valuable preventive of thrombo-embolic accidents. Daily estimations of the prothrombin-time were, he thought, essential for safe therapy, and hæmorrhagic complications were in his experience readily controlled with menadione bisulphite.

Cardiac Surgery

It remains to mention certain surgical measures which have been devised in recent years, some with a view to diverting the blood-stream in heart-failure cases from severely congested areas, others for the instrumental widening of valvular orifices. Several operations to improve the circulatory mechanics in mitral stenosis have been proposed.

In 1923 Cutler performed valvulotomy on five cases of mitral stenosis; the first patient made a good recovery from the operation, improved considerably for a time, and died $4^1/_2$ years later. The other four cases all died shortly after the operation.

In 1925 Souttar performed a finger dilatation of the mitral valve on a patient who had suffered from frequently recurring attacks of congestive heart-failure secondary to long-standing mitral stenosis with regurgitation. The girl made an uncomplicated recovery from the operation, and her report three months later was that she felt perfectly well though still somewhat breathless on exertion.

Brock (1950) has performed valvulotomy on seven patients with mitral stenosis, ranging in age from 22 to 42. All except one were suffering from severe degrees of decompensation, three had recurring attacks of congestive heart-failure, and five had had attacks of pulmonary œdema. Two of the patients died, but five made good recoveries and later reported that they were in regular employment, whereas previously they had been almost completely disabled.

Harken and his colleagues (1948) have described two direct-approach operations—valvuloplasty and fenestration of the interauricular septum—which they have performed in selected cases of mitral stenosis. In broad principle, the objects of valvuloplasty are to increase the size of the mitral orifice by wedge resections of the commissures which fuse with and immobilise the valve leaflets, and to restore such a degree of valvular action as will to some extent control the regurgitant stream. Of the two cases reported by Harken et al., in the first the operation was unsuccessful: there was a postoperative rise, rather than a fall, in the left auricular pressure; pulmonary œdema developed, and the patient died in 24 hours. In this case death was attributed to a rise in the pulmonary blood-pressure primarily due to tachycardia, partly also to increased pulmonary filling from the undamaged right ventricle, and partly to increased regurgitation from the left ventricle. In the second case the clinical indications included a low cardiac output and a diminished stroke-volume on exertion, and it was thought that valvuloplasty would increase the range of cardiac compensation. The operation was successfully performed, the patient made an uncomplicated recovery, and his subsequent improvement was regarded as dramatic.

to the bases of the tubules. The remainder of the epithelium lining the tubules stained faintly with mucicarmine. The epithelium of the surface and the gastric pits stained deeply with mucicarmine.

Clinical Findings

Subject X was aged 25 and weighed 11 st. He had not had dyspepsia. His past history included three mild bouts of benign tertian malaria following three years' Army service, and an attack of tonsillitis with subsequent tonsillectomy at the age of 5 years. His diet had always been good except for two months' poor diet while on Army service in New Guinea. The family history showed that his maternal grandmother had died of pernicious anæmia at the age of about 70. His mother, at the age of 44, had had several months' illness in which weakness and dyspepsia had been the main symptoms. A gruel meal had then showed that she had a low secretion of free acid (less than 20 units), and the amount of mucus had been described as abnormal.

Clinical examination revealed no abnormality. Radiography after a barium meal showed normal gastric emptying time and no abnormality in stomach or duodenum. The findings on the third test-meal were achlorhydria, secretion of 105 ml. in two hours (normal range 81–272 ml., average 134 ml., in 11 controls), secretion of mucus in two hours 107 mg. of reducing substance (Weiden 1949) (normal range in controls 86–440 mg., average 169 mg.), and peptic activity 20 units (accepted normal in this laboratory over 70 units).

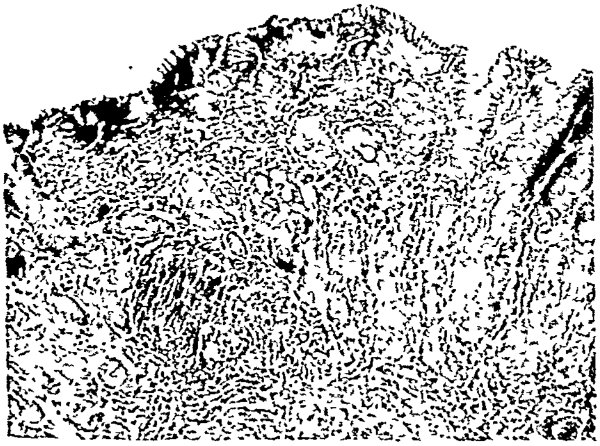

Fig. 2—Biopsy specimen (piece A) from mucosa of body of stomach in a student with persistent histamine-fast achlorhydria and low pepsin index. There is some thinning of mucosa and atrophy of chief and parietal cells. Epithelium of residual tubules now shows mucus secretion with specific mucin stain. There is development of a lymph follicle. (Pepsinogen stain and methyl green.) (×105.)

Examination of the blood revealed the following normal values: red cells 5,200,000 per c.mm., Hb 15·6 g. per 100 ml.; relative volume of packed red cells 43% of the blood: mean corpuscular volume 84 c.μ; mean corpuscular Hb 30 μμg.; leucocytes 5000 per c.mm. (differential count normal).

Gastroscopy was not done.

DISCUSSION

This investigation confirms current opinion on the low incidence of achlorhydria in young adults. It also suggests that achlorhydria has a definite histological abnormality as its cause in healthy people as well as in patients with dyspepsia or related conditions, as we have previously demonstrated (Wood et al. 1949b). This continuing agreement between the histological picture and the biochemical findings, and the similarity of structure when more than one biopsy specimen is obtained from the same patient, make us feel that even one sample is representative of the histological lesion throughout the body of the stomach in gastritis. Though this relation between structure and function has been suggested by other workers, no histological evidence has been brought forward in the case of an apparently normal person. On the contrary, on looking at the mucosa many gastroscopists can see little change, as cited by Palmer (Cecil 1943).

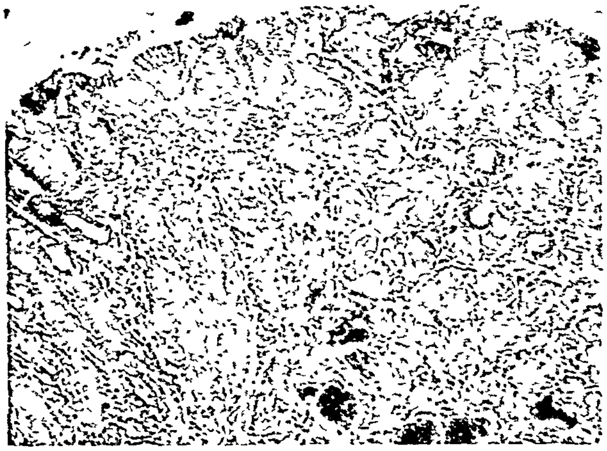

Fig. 3—Biopsy specimen (piece B) from mucosa of body of same stomach as in fig. 2. The portion on the left shows complete atrophy of chief and parietal cells, also seen in piece A (fig. 2). The portion on the right shows a few pepsinogen-containing chief cells at base of tubules. (Pepsinogen stain and methyl green.) (×105.)

Clinically the only ætiological factor to be considered in subject X is a brief period of dietary deficiency three years ago, but our experience with malnutrition does not lead us to believe that this is the cause of the mucosal change in this student. Apart from cases of pernicious anæmia, patients with achlorhydria whom we have studied have always shown a superficial or catarrhal inflammation with polymorph infiltration and surface exudate, and atrophy has depended on the depth of inflammation. In subject X the histological picture was one of gross atrophy of the specific glandular elements of the mucosa of the body of the stomach and macrophage and lymphocyte aggregation about the atrophied areas. An extreme degree of this change—i.e., from almost complete to complete atrophy of chief and parietal cells with minimal catarrhal inflammation—is particularly the case in pernicious anæmia.

SUMMARY

In 134 medical students only one example of persistent histamine-fast achlorhydria was discovered.

Gastric biopsy in 4 students who gave normal results with test-meals showed relatively normal gastric mucosa.

Gastric biopsy in the student with achlorhydria showed an unusual type of atrophy of the specific glandular elements of the gastric glands and an absence of superficial inflammation. In this student no ætiological factor for gastritis was found. There was a family history of pernicious anæmia and of hypochlorhydria on the maternal side. Clinical examination, a barium meal, and examination of the blood all gave normal results. The volume of gastric juice secreted was normal, but free acid was absent and pepsin and mucus were much reduced.

It is felt that persisting achlorhydria, when histamine is used as the stimulus, will always be associated with a diffuse histological change in the mucosa of the body of the stomach, independent of the presence or absence of any symptoms relating to the gastro-intestinal tract or elsewhere.

There has been much speculation concerning the cause of histamine-fast achlorhydria in healthy young adults; but, so far as we know, no previous histological examination of the gastric mucosa in such persons has been made.

There is agreement about the incidence of achlorhydria in healthy young adults. Originally Bennett and Ryle (1921), using the gruel test-meal, found 4 cases of achlorhydria in 100 healthy medical students; in 1934, Lander and Maclagan, using histamine as a more powerful stimulus, found an incidence of 1% in a comparable series. In the present study we found 1 case of histamine-fast achlorhydria in 134 students. Out of eight commonly used textbooks (Wiggers 1944, Best and Taylor 1945, Harrison 1937, Maxwell 1947, Price 1941, Dible and Davie 1945, Boyd 1944, Cecil 1943), only the first four mention the low incidence of histamine-fast achlorhydria in healthy persons.

As regards the cause, both Hurst (Price 1941) and Boyd (1944) suggest that chronic gastritis would always be the basis of persistent achlorhydria irrespective of symptoms, but they provide no histological evidence in "normal" people. Schindler et al. (1940) have demonstrated mucosal abnormalities gastroscopically in 96 of 101 cases of persistent achlorhydria associated with various diseases; but Palmer (Cecil 1943) points out that "in many cases of histamine-proved anacidity in apparently normal individuals the mucosa as seen gastroscopically is essentially normal or shows evidence of relatively slight or patchy inflammation."

The present investigation was carried out to discover young adults with histamine-fast achlorhydria and submit them to gastric biopsy. In the one such person so discovered gastric biopsy revealed extensive changes in the mucosa of the body of the stomach.

MATERIAL

The 134 volunteers were students in the clinical school of the Royal Melbourne Hospital. There were 112 men and 22 women, aged 19–35, the average age being 24. Before volunteering the students were informed that if achlorhydria was detected they would be asked to submit to gastric biopsy. We are most grateful to those students who volunteered for the test-meal and in particular to the student with achlorhydria and the four controls on whom gastric biopsy was done.

TECHNIQUE

A gruel test-meal was given, and specimens were withdrawn at intervals until a secretion of over 10 units of free acid was obtained. If no success was obtained in an hour, the stomach was emptied, and 0·3 mg. of histamine was given, and the procedure repeated; 32 students did not secrete 10 units of free acid with this technique and were retested in the same manner but under improved conditions. In 11 cases the test-meal was done in more detail, and the results were used as a basis for control in this and other studies.

Gastric biopsy was done with a flexible gastric biopsy tube, and the sections were prepared as described by Wood et al. (1949a). There were no untoward reactions, and satisfactory samples were obtained.

INCIDENCE OF ACHLORHYDRIA

All 134 volunteers except one man, "subject X," showed a secretion of 10 units or more of free acid on one or more occasions. Subject X secreted no free acid on either occasion. Three months after the first test-meal a third test-meal was given to this volunteer, with 0·5 mg of histamine as the stimulus. The stomach was completely emptied at 15-minute intervals for two hours. Again achlorhydria was found. The incidence of histamine-fast achlorhydria in young adults, when taken with the results of Lander and Maclagan (1934) in 234 subjects, is 0·85%.

Four students with normal values for free acid were submitted to biopsy and showed body mucosæ within normal limits. A typical example of one of these is shown in fig. 1.

FINDINGS IN SUBJECT WITH ACHLORHYDRIA

Biopsy Findings

At biopsy in subject X two pieces were obtained. In piece A (fig. 2) there was some thinning of the mucosa, and the gastric glands showed gross atrophy of the specific chief and parietal cells. Chief-cell remnants with poorly staining pepsinogen granules were seen at the base of the mucosa. The scanty tubules present were lined with an irregular epithelium which stained faintly with mucicarmine. The lamina propria, especially in the region of the atrophied glands, showed a dense collection of wandering cells of macrophage and lymphocyte types. The lymphocytes were occasionally aggregated into nodules. There was proliferation of young fibroblasts round obvious centres of epithelial necrosis. The muscularis mucosæ was split up, and strands of muscle penetrated between the bases of surviving glands to an abnormal extent. The superficial portion of the lamina propria showed a few plasma cells only, but there was much intercellular hyaline material. The appearance suggested œdema fluid. The overlying mucosa was flat in parts but was chiefly normal and was deeply stained with mucicarmine.

In piece B (fig. 3) the mucosa was a little thicker, but advanced atrophy like that present throughout the first piece was found in only half the section. The remaining half showed normal architecture, but the parietal cells were scanty and poorly staining, and the chief cells with pepsinogen granules were limited

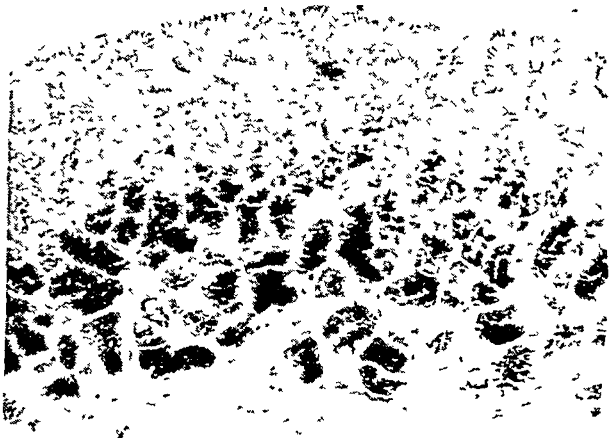

Fig. 1—Biopsy specimen from mucosa of body of stomach in a male student who gave a normal reaction to a histamine test-meal. Section shows normal mucosa. Normal lightly staining parietal cells lie between the chief cells, which are readily identified by their abundant darkly staining pepsinogen granules. (Pepsinogen stain and methyl green.) (×105.)

to the bases of the tubules. The remainder of the epithelium lining the tubules stained faintly with mucicarmine. The epithelium of the surface and the gastric pits stained deeply with mucicarmine.

Clinical Findings

Subject X was aged 25 and weighed 11 st. He had not had dyspepsia. His past history included three mild bouts of benign tertian malaria following three years' Army service, and an attack of tonsillitis with subsequent tonsillectomy at the age of 5 years. His diet had always been good except for two months' poor diet while on Army service in New Guinea. The family history showed that his maternal grandmother had died of pernicious anæmia at the age of about 70. His mother, at the age of 44, had had several months' illness in which weakness and dyspepsia had been the main symptoms. A gruel meal had then showed that she had a low secretion of free acid (less than 20 units), and the amount of mucus had been described as abnormal.

Clinical examination revealed no abnormality. Radiography after a barium meal showed normal gastric emptying time and no abnormality in stomach or duodenum. The findings on the third test-meal were achlorhydria, secretion of 105 ml. in two hours (normal range 81–272 ml., average 134 ml., in 11 controls), secretion of mucus in two hours 107 mg. of reducing substance (Weiden 1949) (normal range in controls 86–440 mg., average 169 mg.), and peptic activity 20 units (accepted normal in this laboratory over 70 units).

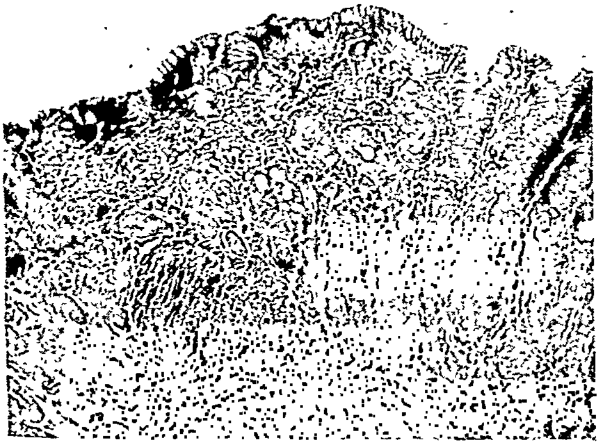

Fig. 2—Biopsy specimen (piece A) from mucosa of body of stomach in a student with persistent histamine-fast achlorhydria and low pepsin index. There is some thinning of mucosa and atrophy of chief and parietal cells. Epithelium of residual tubules now shows mucus secretion with specific mucin stain. There is development of a lymph follicle. (Pepsinogen stain and methyl green.) (× 105.)

Examination of the blood revealed the following normal values: red cells 5,200,000 per c.mm., Hb 15·6 g. per 100 ml.; relative volume of packed red cells 43% of the blood; mean corpuscular volume 84 c.μ; mean corpuscular Hb 30 μμg.; leucocytes 5000 per c.mm. (differential count normal).

Gastroscopy was not done.

DISCUSSION

This investigation confirms current opinion on the low incidence of achlorhydria in young adults. It also suggests that achlorhydria has a definite histological abnormality as its cause in healthy people as well as in patients with dyspepsia or related conditions, as we have previously demonstrated (Wood et al., 1949b). This continuing agreement between the histological picture and the biochemical findings, and the similarity of structure when more than one biopsy specimen is obtained from the same patient, make us feel that even one sample is representative of the histological lesion throughout the body of the stomach in gastritis. Though this relation between structure and function has been suggested by other workers, no histological evidence has been brought forward in the case of an apparently normal person. On the contrary, on looking at the mucosa many gastroscopists can see little change, as cited by Palmer (Cecil 1943).

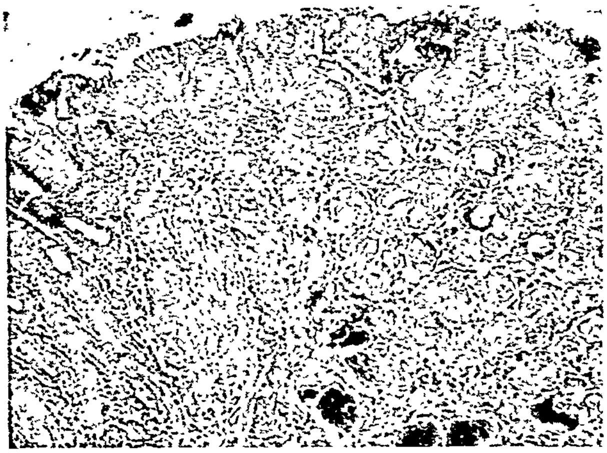

Fig. 3—Biopsy specimen (piece B) from mucosa of body of same stomach as in fig. 2. The portion on the left shows complete atrophy of chief and parietal cells, also seen in piece A (fig. 2). The portion on the right shows a few pepsinogen-containing chief cells at base of tubules. (Pepsinogen stain and methyl green.) (× 105.)

Clinically the only ætiological factor to be considered in subject X is a brief period of dietary deficiency three years ago, but our experience with malnutrition does not lead us to believe that this is the cause of the mucosal change in this student. Apart from cases of pernicious anæmia, patients with achlorhydria whom we have studied have always shown a superficial or catarrhal inflammation with polymorph infiltration and surface exudate, and atrophy has depended on the depth of inflammation. In subject X the histological picture was one of gross atrophy of the specific glandular elements of the mucosa of the body of the stomach and macrophage and lymphocyte aggregation about the atrophied areas. An extreme degree of this change—i.e., from almost complete to complete atrophy of chief and parietal cells with minimal catarrhal inflammation—is particularly the case in pernicious anæmia.

SUMMARY

In 134 medical students only one example of persistent histamine-fast achlorhydria was discovered.

Gastric biopsy in 4 students who gave normal results with test-meals showed relatively normal gastric mucosa.

Gastric biopsy in the student with achlorhydria showed an unusual type of atrophy of the specific glandular elements of the gastric glands and an absence of superficial inflammation. In this student no ætiological factor for gastritis was found. There was a family history of pernicious anæmia and of hypochlorhydria on the maternal side. Clinical examination, a barium meal, and examination of the blood all gave normal results. The volume of gastric juice secreted was normal, but free acid was absent and pepsin and mucus were much reduced.

It is felt that persisting achlorhydria, when histamine is used as the stimulus, will always be associated with a diffuse histological change in the mucosa of the body of the stomach, independent of the presence or absence of any symptoms relating to the gastro-intestinal tract or elsewhere.

AUREOMYCIN IN LYMPHOGRANULOMA INGUINALE

C. D. ALERGANT
M.D. Lpool, M.R.C.P.
CONSULTANT VENEREOLOGIST, NEWSHAM GENERAL HOSPITAL, LIVERPOOL

THE demonstration by Wong and Cox (1948) that 'Aureomycin' was effective against experimental lymphogranuloma inguinale in mice was followed by studies on man.

Early accounts were enthusiastic. Thus, Wright et al. (1948a), who reported on 25 cases of lymphogranuloma inguinale (including 8 with inguinal buboes) treated with aureomycin in a daily dose of 10–20 mg. intramuscularly, found that all showed a reduction in the size of the glands after four days' treatment—"a result which has never been observed to occur spontaneously within so short a time." They clai[illegible]ed equally good results in lymphogranulomatous proctitis, with or without ulceration, and in benign rectal strictu[illegible]. A later account by the same authors (1948b) conta[illegible]ed a similarly favourable conclusion. Benhamou et al. [illegible]1949) have described a single case in which aureomyc[illegible] was administered orally—750 mg. every eight hours. [illegible] was rapid and spectacular, the inguinocrural masses disappearing within six days.

More recently, Robinson et al. (1950) have assessed more critically the value of aureomycin in lymphogranuloma inguinale. They treated 9 patients; 4 received intramuscular injections totalling 0·56–3·6 g. in four to fifteen days, while the remaining 5 received 3·6–38·0 g. orally in five to fifteen days. They concluded that after aureomycin therapy clinical improvement, as measured by healing of genital lesions and reduction in size or complete resolution of buboes, was not impressive. In the patients tested the intradermal test remained positive after treatment; they regarded the complement-fixation test as an unsatisfactory index of therapeutic effect.

CASE-RECORDS

The present series consists of 6 cases. All the patients were adult males suffering from inguinal and/or femoral buboes. Ages ranged from 22 to 44 years. The nationalities of the patients were Chinese (3), Indian (1), Norwegian (1), and British (1). In each case the infection had been acquired abroad—in Hong-Kong in 2 cases, in Batavia in 2 cases, and in Singapore in 1 case. In 1 case linguistic difficulties made it impossible to ascertain the locality in which the infection was acquired.

The lymph-gland enlargement was unilateral in 4 cases, and bilateral in 2. In 2 cases there was accompanying enlargement of the iliac glands on one or other side. In every case the diagnosis was confirmed by a positive Frei test and by a positive complement-fixation t in a titre of 1/40 or higher. Symptoms had been prese for two to eight weeks before the patients came un observation. Only 1 patient had received any previ treatment; he said that on board ship he had receiv a fifteen-day course of tablets (presumably sulphonami without apparent benefit. We gave this patient a thr day course of chloramphenicol 3 g. daily. No improvem could be detected after ten days.

Aureomycin was administered by mouth. A stand dosage was used for the first 5 cases—250 mg. ev six hours to a total of 7 g. The 6th case, described detail below, received two courses of aureomycin, t total of 29 g.

In 4 cases, clinical improvement was gratifying. instance, when the patient who had failed to resp to sulphonamide and chloramphenicol was examined the seventh and last day of treatment there was no p and no visible swelling; the inguinal glands were palpably enlarged, but were firm, discrete, and no lon tender. In the 3 other patients the results were equ good. Pain and tenderness vanished; periadenitis appeared; and within a week of completing treatm all that remained were a few discrete, mobile, pain glands only a little larger than normal.

In the 5th case the clinical result was less satisfact[illegible] month after completion of treatment enlarged gla the[illegible]till readily palpable, and they had not retu were [illegible] size a fortnight later. They were, howe to norma[illegible]e. The iliac glands, originally enlarged, c discrete; and t[illegible]phie[illegible] no longer be felt. [illegible] of [illegible]receiving a much higher do

The 6th case, although [illegible] were [illegible]least satisfactory c than the preceding 5, had t[illegible] [illegible]roliferatio[illegible] response. [illegible]thelial seen on Nov [illegible]ago.

This patient, Chinese, aged 44, was first [illegible] seen on Nov 1949. Treated for primary syphilis four years ago. L to infection at Singapore two or three months [illegible]ons in in groin for eight weeks. A few tiny herpetic les the r coronal sulcus; matted mass of enlarged glands in fem inguinal region; discrete enlargement of the right f glands; large mass of glands palpable in the right iliac no clinical signs of syphilis. Frei test positive; Wasse reaction positive; lymphogranuloma inguinale complem fixation test positive 1/320.

Treatment.—Aureomycin 500 mg. 6-hourly—double dosage used in previous cases—was begun immediately, had to be discontinued after two days owing to a tempo shortage of the drug. A fresh supply was secured, and tr ment was continued to a total of 14 g. Two days a completion of treatment, the inguinal glands were a li smaller but were still matted together. The iliac glands formed a palpable mass in the iliac fossa.

No further aureomycin was administered for a mon During this time, 'Bisoxyl' 1·2 g. and crystalline penicilli 5 mega-units were administered, because of the latent syphi without any apparent effect on the lymphogranuloma inguina

On Jan. 11, it was decided to administer a further cou of aureomycin, and 250 mg. were given 6-hourly for fifte days. There followed a further slow decrease in the size the inguinal and iliac gland masses.

On Feb. 9, the iliac glands were still readily palpable, a there was still a thickened ridge along the fold of th right groin, persisting periadenitis making it impossible distinguish individual glands.

When treatment was completed, all patients were kep under observation for a period of six to fourteen week in an attempt to discover the behaviour of the Frei an lymphogranuloma inguinale complement-fixation test after treatment with aureomycin; during this perio both tests were performed at short intervals.

An initial difficulty with the Frei test was that patients repeated testing appeared to become sensitised to e constituent of egg embryo, developing large o reactions in the control arm. Subsequently, antigen was prepared according to Frei's original -patient became Frei-negative; 2 patients

eventually gave doubtful reactions, 1 some three months, and the other one month, after completion of treatment. The other 4 all remained Frei-positive six to twelve weeks later. These comprised 3 cases regarded as clinically cured, and the 6th case reported above.

The behaviour of the lymphogranuloma inguinale complement-fixation test after treatment was equally disconcerting. In one case the titre, initially 1/80, dropped to 1/10 three days after treatment was completed, fluctuated between 1/10 and 1/5 for a further two months, and became negative at 1/5—the lowest dilution tested—by the end of three months. In another case, where the clinical result was equally satisfactory, the titre was initially 1/120, and it remained at this level for several weeks; but two months after completion of treatment the titre had risen to 1/320. Although there seemed to be no correspondence between clinical and serological results, the 2 cases with doubtful Frei tests after treatment both showed the most significant drop in the titre of the complement-fixation test—from positive 1/80 to negative 1/5, and from positive 1/160 to positive 1/40. No other case showed a drop to less than half the original titre—i.e., a change of more than one tube.

SUMMARY

Six cases of lymphogranuloma inguinale have been treated with aureomycin, and four showed a good clinical response.

These cases were kept under observation for 6–14 weeks after treatment, and the results of serial Frei and lymphogranuloma inguinale complement-fixation tests are recorded. No case became Frei-negative.

I am indebted to Dr. L. A. Little, of the department of bacteriology, University of Liverpool, for the results of the lymphogranuloma inguinale complement-fixation tests. I wish to thank Dr. A. O. F. Ross for allowing me to treat some of his cases and for valuable advice. Thanks are also due to Mr. R. J. Ousby without whose assistance it would not have been possible to follow up some of the cases.

EOXYCORTONE AND ASCORBIC ACID IN THE TREATMENT OF RHEUMATOID ARTHRITIS

E. G. L. BYWATERS
F.R.C.P.

A. ST. J. DIXON
M.D. Lond., M.R.C.P.

J. B. WILD
M.D. Lond., M.R.C.P.

rom the Special Unit for Study and Care of Juvenile heumatism, Canadian Red Cross Memorial Hospital, Taplow, ucks, and the Department of Medicine, Postgraduate Medical School of London

IN view of our failure to observe any obvious bedside provement in patients with rheumatoid arthritis ter the injection of ascorbic acid and deoxycortone etate, following the technique recommended by Lewin d Wassén (1949), and in view of the numerous claims at such improvement does result (Le Vay and Loxton 949, Loxton and Le Vay 1949, Spanopoulos 1950, ox 1949, Landsberg 1950, Robertson 1950, Nashat 50, Fox 1950, Douthwaite 1949, Le Vay and Loxton)), we have followed ten patients more closely, with [illegible] analysis of some of the responses.

METHOD

riteria for selection of patients included an erythro e-sedimentation rate above 25 mm. in 1 hour (Westergren), and radiological signs of bone and cartilage destruction. The disease had been present for 1 to 10 years.

Assessment included, besides an inquiry into symptoms, and a daily diary kept by 4 of the patients: (*a*) measurement of strength of grip in mm. Hg (in patients with wrist involvement): (*b*) measurement of the angles of flexion and extension of the knees or other involved joints; (*c*) assessment of pain on pressure over a joint (graded 0–3); and (*d*) functional tests, such as the measurement of time to put on or take off a certain garment, walk a certain distance, or write a test sentence, or of the number of stitches knitted in 2 minutes. The angles of knee movement were measured in duplicate. Two strips of wood, hinged together at one end, were aligned with bony points (marked in indelible ink) on the outer malleolus, outer condyle of tibia, and greater trochanter. The angle was then drawn on paper and was measured later. This ensured a "blind" measurement. Direct eosinophil-counts were done 3 hours after the injection.

TABLE I—IMMEDIATE EFFECTS OF DEOXYCORTONE ACETATE AND ASCORBIC ACID INJECTION, COMPARED WITH PROCAINE AND SALINE

Injection	Walking-time (sec.)		t*
	Before	After	
Saline	50·0 ±6·3	48·5 ±7·6	0·3
Deoxycortone acetate and ascorbic acid	57·0 ±4·3	52·0 ±4·8	1·9
Procaine	47·3 ±5·5	44·5 ±4·6	1·3

* 2 45 for p = 0·05.

Similar findings with left-handed and right-handed strength, knitting-time, and eosinophil-count.

EXPERIMENTS

The plan of the first experiment was as follows:

After preliminary familiarisation of the three patients with the methods of measurement, and a week or so under hospital conditions, an injection (of a substance unknown to the patient) was made at 10.55–11 A.M. each day, preceded by a battery of measurements at 10.15 A.M. and 10.45 A.M. and followed by the same measurements at 11.15 A.M. and again at 11.45 A.M. The substances used were saline intravenously (2 ml.): procaine intravenously (4 mg. per kg. body-weight in 200 ml. of saline in 20 min.); and deoxycortone acetate 5 mg. intramuscularly (or 5 mg. of the glucoside intravenously) and ascorbic acid 1 g. intravenously.

The results showed no significant change after either saline, procaine, or deoxycortone acetate and ascorbic acid. Representative readings, given in table I and in fig. 1, show three replications of each type of treatment in one of the three patients. Evaluation was by the ratio of the difference between the means of each measurement before and after each type of drug to the standard

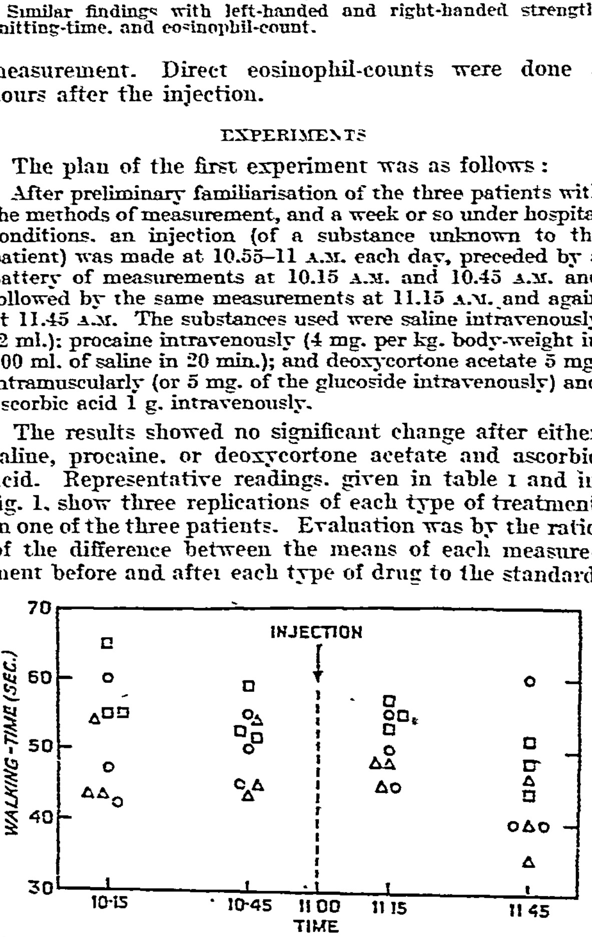

Fig. 1—Immediate effects of deoxycortone acetate and ascorbic acid injection, compared with procaine and saline, expressed diagrammatically. Circles = saline; squares = deoxycortone acetate and ascorbic acid; triangles = procaine.

TABLE II—ANALYSIS OF VARIANCE IN 3 PATIENTS RECEIVING SALINE, DEOXYCORTONE ACETATE AND ASCORBIC ACID, OR PROCAINE

Variance	Sum of squares of deviation from mean	Degrees of freedom	Mean square
etween patients ..	35·39	2	17·6
tween days	8·18	2	4·1
ween treatments ..	5·93	2	3·0
r	383·89	29	13·2
otal	433·39	35	..

Ratio of mean squares "between-treatments/error" should be 3 or more to be significant. On the second complete replication, ratio of mean squares was 0 3. compared with 0·2 for the iment detailed above.

of that difference. Values of *t* were obtained for e, deoxycortone acetate and ascorbic acid, and caine well below the minimum required for p = 0·05. o significant change in eosinophils was seen.

Because there was some day-to-day variation in base-line readings, which might have masked small but significant differences, a second experiment was made, of a Latin-square design, where three patients with hand and wrist involvement had three different treatments (saline, deoxycortone acetate and ascorbic acid, and procaine) on each of three different days. Readings of hand-grip were made in duplicate before and one hour after each injection. Changes in left and right grips after injection showed no significant difference and hence were treated as two further replications. An analysis of variance (with 35 degrees of freedom) showed that neither the variance between persons, days, or treatments reached significance (table II). This whole trial has been repeated once again with the same patients, the same treatments (except that the dose of procaine was doubled), and the same results.

Independent analyses by two observers of the diary kept by the most reliable of the patients treated and the most "objective" self-observer, showed remarkable agreement. There was little difference between the effects of procaine, saline, and deoxycortone acetate and ascorbic acid. Thus of the 18 days of the trial, moderate improvement was noted on 3 days (2 of which followed procaine and 1 deoxycortone acetate plus ascorbic acid); on 6 days slight improvement was noted (4 following deoxycortone acetate and ascorbic acid and 2 following saline). No change occurred on 8 days (following procaine on 3 days, saline on 4 days, and deoxycortone acetate and ascorbic acid on 1 day). She became worse on 1 day only (following procaine). Although there was some relationship between objective and subjective improvement, this was not constant. The highest grade of subjective improvement coincided on only 1 day with the highest grade of objective improvement, and that followed a procaine injection. The patient left hospital after 7 weeks greatly improved—as she had done also after her previous admission in 1948.

Three cases of established rheumatoid arthritis in children were studied in respect of numerous functions before and after injections of saline, and of deoxycortone acetate and ascorbic acid. No significant objective change occurred in either the clinical observations or the measured functions. One of these patients had previously shown a good response to adrenocorticotropic hormone (A.C.T.H.) (which had also, of course, been substituted after an 8-day control period of saline injections).

FURTHER TRIAL

A longer trial of deoxycortone acetate and ascorbic acid in three patients with rheumatoid arthritis was made at the Postgraduate Medical School of London. Fig. 2 illustrates observations on a patient who had had rheumatoid arthritis for 4 years. It will be seen that all criteria improved on the first few days of saline injection, and that no further improvement occurred when deoxycortone acetate and ascorbic acid was substituted (given three times daily for 3 days). Two other patients, studied in the same way, showed exactly the same results.

Finally, we have administered deoxycortone acetate and ascorbic acid on 3 days, and saline on 3 days, to a patient with severe rheumatoid arthritis who had previously undergone an immediate and dramatic remission with A.C.T.H. and who had relapsed after cessation. The patient had a very good idea what subjective improvement he might expect, but neither subjective nor objective improvement was noted in either degree or rapidity of joint movement.

CONCLUSION

We are well aware that statistically negative results like this do not prove that the treatment is without effect: the wrong criteria may have been selected. In our trials of A.C.T.H., a number of criteria have shown no significant change; other criteria have shown significant improvement. We think that in the present cases, however, any real improvement, even if unnoticed by the patient or by the observer, would have been revealed by the several tests that we chose.

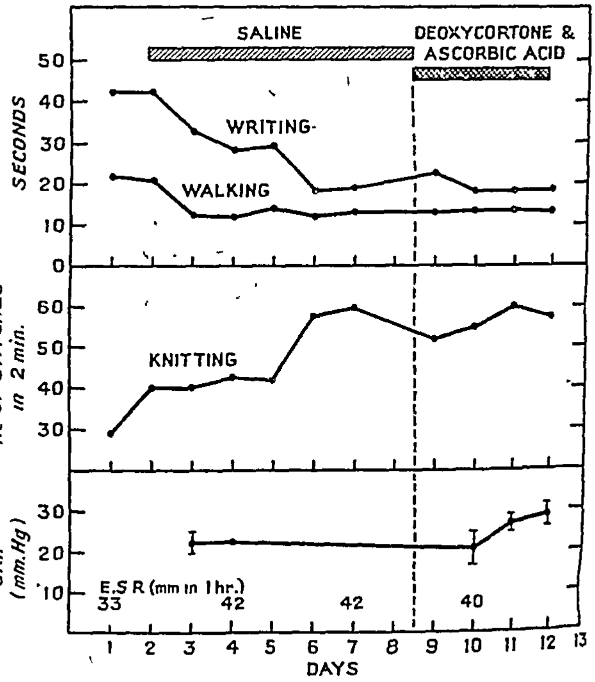

Fig. 2—Effects of deoxycortone acetate and ascorbic acid injections thrice daily.

We conclude, therefore, from this limited but intensive experience—and in common with Kellgren (1949), Spies et al. (1949), Hart and Starer (1949), Fletcher et al. (1950), Hartfall and Harris (1949), Kersley et al. (1950), and Currie and Will (1950)—that deoxycortone and ascorbic acid has no immediate measurable or appreciable effect on rheumatoid arthritis beyond that which follows any non-specific injection or treatment, and that it is not in any way comparable to A.C.T.H. While it is a thankless and even dangerous task to try to account for other investigators' results, we might perhaps suggest that the substitution of the drug to be tested in place of preliminary saline injections, unknown to the patient, and if possible also to the nurses, is an essential requirement of a careful study. The path of therapeutic advance is strewn with the bones and the bottles of those who have neglected such precautions.

Dr. L. G. C. Pugh, Dr. M. Keech, and Dr. E. Dresner assisted in some of these observations; Dr. D. Mitchison gave valuable help with statistical analysis.

FLAXEDIL AS AN ADJUVANT IN GENERAL ANÆSTHESIA

PARTICULARLY WITH NITROUS OXIDE AND INTRAVENOUS PETHIDINE

J. SHEGOG RUDDELL
M.A., M.B. Dubl., D.A.
ANÆSTHETIST, KUWAIT OIL COMPANY HOSPITAL,
PERSIAN GULF

AFTER having a considerable experience with *d*-tubocurarine as a muscle relaxant and fully appreciating its value in general anæsthesia, my attention was drawn to 'Flaxedil'—tri-(β-diethylaminoethoxy)-benzene triethodide—by the preliminary report of Mushin et al. (1949). Flaxedil has the advantage of being miscible with thiopentone, but if it is to take the place of *d*-tubocurarine it must also be equally effective and free from qualities which might be undesirable. In an attempt to assess its relative value careful records have been kept in the 440 successive cases in which it has been administered.

OPERATIONS AND GENERAL ANÆSTHETICS GIVEN

Operation	*Cyclo-propane*	*Pethidine and N_2O*	*Trichlor-ethylene*	*Thio-pentone*	*Total*

INDUCTION AND PREMEDICATION

Of these cases, 386 were induced with, and intubated by direct vision under, thiopentone and flaxedil mixed in the same syringe. Intubation has invariably been easy, and in no case has there been any spasm of the glottis or bronchospasm.

The technique is as follows: 15–20 ml. of a 5% solution of thiopentone, the amount depending on the patient's physical condition, is drawn into a syringe, followed by 2 ml. of a 4% solution of flaxedil. This mixture is administered over $2^1/_2$–3 minutes, and a pause of 1 minute is made to allow the flaxedil to exert a sufficient effect for intubation to be performed through either the mouth or the nose.

In 4% of the cases—females—2 g. of thiopentone dissolved in 2 oz. of water was run into the rectum an hour before operation. When the patient became drowsy gr. $^1/_{100}$ of atropine was given intramuscularly. All these patients arrived in the anæsthetic room either asleep or very drowsy; there they received either 5 or 10 ml. of a 5% solution of thiopentone mixed with 2 ml. of a 4% solution of flaxedil and were intubated.

The premedication in all other cases was morphine gr. $^1/_6$ and atropine gr. $^1/_{100}$ given intramuscularly three-quarters of an hour before operation.

In no case induced by either of these methods was there any respiratory depression requiring more than assisted respiration, and this became unnecessary once surgical stimulation had started.

MAINTENANCE

The effect of 80 mg. of flaxedil lasted on an average 20 minutes, and a further 40 or 80 mg. was given when required. In 60% of the cases in which flaxedil was repeated assisted respiration was necessary for an average of 5 minutes; in the remaining 40% it was not needed. The effect of the second dose was apparent in 20 seconds and lasted up to half an hour, but spontaneous respiration was always adequate after 10 minutes.

In abdominal cases it has been found advantageous to give 40 mg. of flaxedil when the peritoneum is being closed. This does not interfere with respiration but provides relaxed recti abdominis muscles and is greatly appreciated by the surgeon.

Continuous Thiopentone

Early in the present series 15 cases were operated on under continuous thiopentone with flaxedil, but this technique was discontinued because the only safe method of watching the respirations seemed to be to administer oxygen through a rebreathing bag. The addition of an anæsthetic gas has removed the need for continuous thiopentone.

Cyclopropane; Trichlorethylene

There is nothing to note regarding the use of flaxedil with cyclopropane or with trichlorethylene except its general advantage over *d*-tubocurarine in being miscible with thiopentone, quick in action, more transient, not cumulative, and showing no histamine effects and no increased bleeding.

Thiopentone and Intravenous Pethidine

The 129 cases which had nitrous oxide, flaxedil, and intravenous pethidine came at the end of the series, and it is felt that this method approaches the ideal. By the judicious use of these three drugs narcosis is pin-pointed with nitrous oxide, relaxation is achieved with flaxedil, and the analgesic effect of nitrous oxide is supplemented with pethidine.

The technique adopted is essentially that outlined by Mushin and Rendell-Baker (1949), except that the initial dose of pethidine given is 50 mg. The patient is induced with and intubated under thiopentone and flaxedil and put on a mixture of nitrous oxide and oxygen, the proportion of nitrous oxide varying from 75% to 80%. The initial dose of pethidine 50 mg. is given as the patient is being draped.

The very close watch that has to be kept on the patient's pulse-rate, respirations, and blood-pressure may be more exacting for the anæsthetist but is more than compensated for by the absence of postoperative complications. There was no postoperative vomiting in this series, only two patients had a slight moist cough, and none had atelectasis. Postoperative restlessness, which is associated with rapid recovery of consciousness, was noted in only one patient, an Arab who had had numerous plastic operations and thoroughly enjoyed making a noise to show how quickly he recovered. The absence of postoperative chest complications may not be so significant as it appears, because they are comparatively rare here, possibly owing to the climate. There has been no venous thrombosis due to intravenous therapy.

Major operations such as hemicolectomy, hysterectomy, resection of dilated ureter, nephrectomy, lobectomy, *thoracoplasty, partial gastrectomy, and partial thyroid*ectomy have all been done under this form of anæsthesia successfully and with no postoperative complications. The pethidine does not abolish respirations, but it produces a quiet and regular respiratory exchange owing to deepening of anæsthesia.

BRONCHOSCOPY

The 50 bronchoscopies done under anæsthesia induced with thiopentone mixed with flaxedil were all very simple in execution. The patient was given flaxedil 80 mg. mixed with thiopentone 1 g. over $2^1/_2$–3 minutes, and a pause of 2 minutes was allowed before the operation began. The bronchoscope was passed with the patient lying on his back with his head raised on a pillow, and the bronchoscope was passed with the aid of a laryngoscope. If a sufficient pause is not made after the administration of the thiopentone and flaxedil, the patient will "buck." On one occasion a second dose of flaxedil 80 mg. had to be given before the bronchoscope could be passed.

SUMMARY AND CONCLUSIONS

Flaxedil has been used as a muscle relaxant in 440 cases of general anæsthesia.

Flaxedil has the advantages over *d*-tubocurarine of being miscible with thiopentone and more rapid and more transient in action. It is not cumulative, and it does not *seem to increase bleeding.*

Nitrous oxide as a narcotic, with intravenous pethidine to supplement its analgesic properties and flaxedil as a muscle relaxant, gives a general anæsthesia approaching the ideal.

Attention is also drawn to the use of flaxedil with thiopentone for intubation and bronchoscopy.

I wish to thank Mr. M. G. Allen-Mersh, the surgeon for whom these anæsthetics were given, for his cooperation.

THE HYPOPHYSIS IN RHEUMATOID ARTHRITIS

A. G. EVERSON PEARSE

M.A., M.B. Camb.

ASSISTANT LECTURER IN PATHOLOGY, POSTGRADUATE MEDICAL SCHOOL OF LONDON

IT is usually considered that in rheumatoid arthritis there is no primary endocrine dysfunction. This belief rests mainly on the normal responses of persons with rheumatoid arthritis to various hormones and hormone fractions, and on the essentially normal figures obtained in those hormone assays which have been attempted. The therapeutic action of adrenocorticotropic hormone (A.C.T.H.) and 'Cortisone' is apparently considered to be a non-specific action on collagen. Lichtwitz (1942), however, stated that in "endogenous arthritis" many of his patients had well-marked signs of pituitary disorder, some being acromegalic while others showed features belonging to Simmonds's disease.

In view of the work now being done on rheumatoid *arthritis, the finding of a specific hypophyseal abnor*mality is of interest. Ten pituitary glands from cases indexed in the departmental post-mortem register as rheumatoid arthritis, and three from cases of lupus erythematosus disseminatus have been examined by the older staining techniques of Mallory and Gram together with the newer method described by Pearse (1949, 1950) and other cytochemical methods.

DEFINITIONS

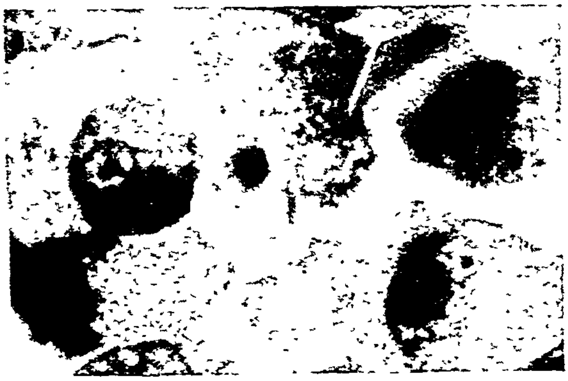
It has become necessary to make some new definitions in pituitary cytological terminology.

(1) The mucoprotein granules which were identified with the beta granules (Pearse 1949) must be divided into beta and gamma granules. The beta granules are stained by the periodic-acid-Schiff method (Hotchkiss 1948); they are also gram-positive and stain positively by the coupled tetrazonium reaction of Mitchell (1942) and Danielli (Danielli and Brown 1947) after as much as sixteen hours' benzoylation. This last reaction is considered to indicate that the beta granules are composed of polymerised mucoprotein, probably associated with ribonucleic acid. The gamma granules are periodic-acid-Schiff-positive only and are considered to be composed of depolymerised mucoprotein alone.

(2) Cells containing beta or gamma granules are referred to collectively as mucoid cells. It will be realised that the basiphils of the older nomenclature are mucoid cells containing beta granules, while a variable proportion of chromophobes (old terminology) contain gamma granules and *therefore belong to the mucoid series.*

In nine of the ten cases of rheumatoid arthritis identical abnormalities of the mucoid cells were present. In the tenth case (spondylitis ankylopoietica) and in two of the three cases of lupus erythematosus they were absent. Eight of the nine cases were shown clinically or at necropsy to be in an active stage of the disease. There is no record of the joint condition in one case of long-standing arthritis in a man of 43, but he was still receiving physiotherapy at the time of his death. No "burnt out" cases—that is, cases in which the disease could be presumed on clinical and pathological grounds to be inactive—have yet been examined. There were no cases of rheumatoid arthritis in which the changes were *not found in* some degree; *it is probable* that they would be absent from the hypophyses of completely inactive cases. The changes, which in all cases occurred diffusely throughout the gland, in three cases were also present in small adenomata, with a diameter of 0·2–1·0 mm., composed entirely of abnormal cells. They consist of partial and eventually *complete* degranulation of the mucoid cells as regards mucoprotein granules, leaving the remainder of the cell partly or completely filled with granules composed of a simple protein with stronger basic properties than those of the protein of normal chromophobe granules.

The diffusely occurring cells, which are partly filled with gamma granules and partly with simple protein granules, have been identified with a type of "abnormal transitional basiphil" described by Crooke and Russell (1935) and found in large numbers in the hypophysis in Addison's disease. They must not be confused with the hyaline basiphils of Crooke (1935), characteristic of Cushing's syndrome and allied disorders. In the adenomata, however, and to some extent outside them, a more striking cellular change was found which has been called polar bigranulation. Such polar bigranulate cells are illustrated in the accompanying photomicrograph. The polarity of the change is dissimilar in adjacent cells and cannot be due to fixation artefact. One half of the cell, top or bottom, left or right, is filled with beta granules, and the other half with simple protein granules identical in character with those found in Crooke-Russell cells. Differential counts of the types of mucoid cell present in four of the glands showed that 18–25% were either Crooke-Russell or polar bigranulate.



Section (5μ) of human hypophysis from a case of active rheumatoid arthritis. Four polar bigranulate mucoid cells can be seen. The contrast between the dark-staining mucoprotein beta granules and the lighter-staining simple protein granules shows well with this stain. (Mallory's trichrome ; × 1050.)

Over 200 control glands were examined, and apart from cases of Addison's disease, where even larger numbers of Crooke-Russell cells and polar bigranulate cells containing gamma instead of beta granules were seen, the former cells were present only in a few cases in the older age-groups. Single polar bigranulate cells were only exceptionally observed in control glands.

Since the number of mucoid cells in active production is considerably lowered in the majority of cases of rheumatoid arthritis, it may be expected that the amount of follicle-stimulating hormone in the hypophysis, and possibly the urinary excretion of that hormone in these cases, will be below the normal levels, perhaps rising to the normal figure in periods of remission if these are reflected in the function of the hypophysis.

SUMMARY

It is considered that a specific change affects the mucoid cells (basiphils, cyanophils) in rheumatoid arthritis which is closely related to the changes seen in Addison's disease. The abnormal appearances of the mucoid cells in both conditions are considered to be secondary to suprarenal dysfunction, whether they are induced directly or indirectly. They indicate, so far as the hypophysis is concerned, that rheumatoid arthritis has some affinity to conditions of suprarenal underaction but none to those of suprarenal overaction (Cushing's syndrome, virilism).

Medical Societies

BRITISH ORTHOPÆDIC ASSOCIATION

THE association's spring meeting was held in Cardiff on April 21 and 22, under the presidency of Mr. S. L. HIGGS.

End-results of fracture of the patella.—Mr. J. V. TODD (Newcastle upon Tyne) reviewed the results of 46 cases of fracture of the patella—16 treated by suture with catgut, and 30 by excision of the patella. Good or excellent results (judged by function, movement, and capacity for work) were gained in 68% of the cases treated by suture and in 80% of those treated by excision. In general, movement was slightly better after excision, but power was better after suture. Mr. K. H. PRIDIE (Bristol) advocated repair of transverse fractures by a single vertical screw. This afforded better apposition and fixation than suture with catgut and allowed movement to be begun immediately. Mr. F. G. BADGER (Birmingham) thought that extension lag was liable to develop if the plaster was removed early after excision; he advised immobilisation for six weeks. Suture was undertaken only in the younger patients. Excision of the smaller fragment, leaving the larger, was capable of giving results equal to the best results of suture and had a place in the treatment of selected cases. Mr. E. N. WARDLE (Liverpool) believed that extension lag after excision could be prevented by care in the postoperative treatment. Flexion movements should not be begun until the power of active straight-leg raising had been regained.

Manubriosternal joint in ankylosing spondylitis.—Mr. D. L. SAVILL (Edinburgh) had studied the condition of the manubriosternal synchondrosis in 61 cases of ankylosing spondylitis, and had found evidence of pathological changes in 72%. Radiographically the joint was shown best by a lateral projection. Normally, the bony margins of the joint were smooth, slightly convex, and separated by a clear cartilage-space. When the joint was affected in ankylosing spondylitis, there was progressive narrowing of the cartilage and erosion of the bone ends. The process was limited by a narrow zone of sclerosis, and the joint line was increased in depth anteroposteriorly. In the later stages the joint was obliterated completely by bony ankylosis. These changes were essentially similar to those occurring in the sacro-iliac joints. Of 22 patients with rheumatoid arthritis, the manubriosternal joint was normal radiographically in 13, slightly narrowed in 4, and partly or completely fused in 5; erosion of the bone ends was not observed. Histological examination of the joint surfaces in ankylosing spondylitis showed, in the areas of erosion, replacement of bone by collagenous fibrous-tissue, without inflammatory reaction. These changes were absent in rheumatoid arthritis.

Hip in fibrous dysplasia.—Mr. A. C. BINGOLD (Leeds) showed radiographs of 5 cases in which the bones in the region of the hip-joint were affected by fibrous dysplasia of the monostotic or polyostotic type.

Pseudarthrosis of the tibia.—Mr. BRYAN MCFARLAND (Liverpool) discussed the results in 9 cases of pseudarthrosis of the tibia treated by the "by-pass" bone-grafting operation described by him in 1940.[1] The operation had been successful in securing bony union in 7 patients, and unsuccessful in 2. The 2 failures were probably due to technical errors: in 1 case the lower end of the graft was notched into the tibia too

and put on a mixture of nitrous oxide and oxygen, the proportion of nitrous oxide varying from 75% to 80%. The initial dose of pethidine 50 mg. is given as the patient is being draped.

The very close watch that has to be kept on the patient's pulse-rate, respirations, and blood-pressure may be more exacting for the anæsthetist but is more than compensated for by the absence of postoperative complications. There was no postoperative vomiting in this series, only two patients had a slight moist cough, and none had atelectasis. Postoperative restlessness, which is associated with rapid recovery of consciousness, was noted in only one patient, an Arab who had had numerous plastic operations and thoroughly enjoyed making a noise to show how quickly he recovered. The absence of postoperative chest complications may not be so significant as it appears, because they are comparatively rare here, possibly owing to the climate. There has been no venous thrombosis due to intravenous therapy.

Major operations such as hemicolectomy, hysterectomy, resection of dilated ureter, nephrectomy, lobectomy, thoracoplasty, partial gastrectomy, and partial thyroidectomy have all been done under this form of anæsthesia successfully and with no postoperative complications. The pethidine does not abolish respirations, but it produces a quiet and regular respiratory exchange owing to deepening of anæsthesia.

BRONCHOSCOPY

The 50 bronchoscopies done under anæsthesia induced with thiopentone mixed with flaxedil were all very simple in execution. The patient was given flaxedil 80 mg. mixed with thiopentone 1 g. over $2^1/_2$–3 minutes, and a pause of 2 minutes was allowed before the operation began. The bronchoscope was passed with the patient lying on his back with his head raised on a pillow, and the bronchoscope was passed with the aid of a laryngoscope. If a sufficient pause is not made after the administration of the thiopentone and flaxedil, the patient will "buck." On one occasion a second dose of flaxedil 80 mg. had to be given before the bronchoscope could be passed.

SUMMARY AND CONCLUSIONS

Flaxedil has been used as a muscle relaxant in 440 cases of general anæsthesia.

Flaxedil has the advantages over *d*-tubocurarine of being miscible with thiopentone and more rapid and more transient in action. It is not cumulative, and it does not seem to increase bleeding.

Nitrous oxide as a narcotic, with intravenous pethidine to supplement its analgesic properties and flaxedil as a muscle relaxant, gives a general anæsthesia approaching the ideal.

Attention is also drawn to the use of flaxedil with thiopentone for intubation and bronchoscopy.

I wish to thank Mr. M. G. Allen-Mersh, the surgeon for whom these anæsthetics were given, for his cooperation.

THE HYPOPHYSIS IN RHEUMATOID ARTHRITIS

A. G. EVERSON PEARSE
M.A., M.B. Camb.
ASSISTANT LECTURER IN PATHOLOGY,
POSTGRADUATE MEDICAL SCHOOL OF LONDON

IT is usually considered that in rheumatoid arthritis there is no primary endocrine dysfunction. This belief rests mainly on the normal responses of persons with rheumatoid arthritis to various hormones and hormone fractions, and on the essentially normal figures obtained in those hormone assays which have been attempted. The therapeutic action of adrenocorticotropic hormone (A.C.T.H.) and 'Cortisone' is apparently considered to be a non-specific action on collagen. Lichtwitz (1942), however, stated that in "endogenous arthritis" many of his patients had well-marked signs of pituitary disorder, some being acromegalic while others showed features belonging to Simmonds's disease.

In view of the work now being done on rheumatoid arthritis, the finding of a specific hypophyseal abnormality is of interest. Ten pituitary glands from cases indexed in the departmental post-mortem register as rheumatoid arthritis, and three from cases of lupus erythematosus disseminatus have been examined by the older staining techniques of Mallory and Gram together with the newer method described by Pearse (1949, 1950) and other cytochemical methods.

DEFINITIONS

It has become necessary to make some new definitions in pituitary cytological terminology.

(1) The mucoprotein granules which were identified with the beta granules (Pearse 1949) must be divided into beta and gamma granules. The beta granules are stained by the periodic-acid-Schiff method (Hotchkiss 1948); they are also gram-positive and stain positively by the coupled tetrazonium reaction of Mitchell (1942) and Danielli (Danielli and Brown 1947) after as much as sixteen hours' benzoylation. This *last reaction is considered to indicate that the beta granules* are composed of polymerised mucoprotein, probably associated with ribonucleic acid. The gamma granules are periodic-acid-Schiff-positive only and are considered to be composed of depolymerised mucoprotein alone.

(2) Cells containing beta or gamma granules are referred to collectively as mucoid cells. It will be realised that the basiphils of the older nomenclature are mucoid cells containing beta granules, while a variable proportion of chromophobes (old terminology) contain gamma granules and therefore belong to the mucoid series.

In nine of the ten cases of rheumatoid arthritis identical abnormalities of the mucoid cells were present. In the tenth case (spondylitis ankylopoietica) and in two of the three cases of lupus erythematosus they were absent. Eight of the nine cases were shown clinically or at necropsy to be in an active stage of the disease. There is no record of the joint condition in one case of long-standing arthritis in a man of 43, but he was still receiving physiotherapy at the time of his death. No "burnt out" cases—that is, cases in which the disease could be presumed on clinical and pathological grounds to be inactive—have yet been examined. There were no cases of rheumatoid arthritis in which the changes were not found in some degree; it is probable that they would be absent from the hypophyses of completely inactive cases. The changes, which in all cases occurred diffusely throughout the gland, in three cases were also present in small adenomata, with a diameter of 0·2–1·0 mm., composed entirely of abnormal cells. They consist of partial and eventually complete degranulation of the mucoid cells as regards mucoprotein granules, leaving the remainder of the cell partly or completely filled with granules in plaster and 50 by simple strapping. The average period of incapacity was eleven and a half weeks for patients treated in plaster, and only six weeks for patients treated by strapping. The slower rate of recovery with the plaster method was probably due to loss of the normal pump action of the muscles (and consequent œdema) while in plaster, and to interruption of the normal walking habit. The patient had to recover from the immobilisation as well as from the fracture. Fractures of this type should be treated by strapping. Mr. H. Osmond-Clarke said that if treatment was to be by strapping, it was necessary to be quite sure that the fracture was stable. Mr. V. H. Ellis doubted whether working time was saved by avoiding plaster; many patients were able to return to work in plaster who otherwise would be unwilling to do so because of pain. Mr. P. H. Wiles and Mr. W. D. Coltart favoured plaster immobilisation.

DEVON AND EXETER MEDICO-CHIRURGICAL SOCIETY

Obesity

Addressing the society on April 20, Dr. P. M. F. Bishop remarked that the conventional view that obesity was due to overfeeding was correct in many cases. Of 300 cases of obesity selected at random at Guy's Hospital, at least 50% were eating too heartily for the amount of work they were doing. As a rule, therefore, curtailment of diet was the essential of treatment; less commonly obesity was an endocrine problem.

On a diet of 1000 calories a day it was possible to do an average day's work, but it might be necessary to reduce the diet to 750 calories a day. Patients were required to weigh themselves weekly and to report at the end of two months. If there had been little or no reduction in weight it was necessary to admit the patient to hospital and starve him, limiting the fluid intake to $1^{1}/_{2}$ pints daily; after twenty-four hours of this régime appetite diminished greatly. Experience had shown that this apparently drastic method of treatment was in fact kinder than giving a niggling diet. With loss of appetite, associated unhappiness and discomfort was dispelled; it was then comparatively easy for patients to accept a 750-calorie diet, on which they would lose weight steadily. Weight-charts generally showed a rapid fall during the first ten days, after which the curve flattened out; 1–3 stone might be lost in the first fortnight. The treatment could not be carried out at home because individual care was necessary. Ketone bodies might appear in the urine, but they disappeared if a little sugar was given.

Diuresis was a valuable adjunct to treatment. Thyroid was useful, especially in myxœdematous subjects. If *d*-amphetamine sulphate was used, it should be given in 10 mg. doses before breakfast and lunch. Where there was fluid retention, ammonium chloride in 10 mg. capsules once or twice daily, a heaped teaspoonful of urea flavoured with lemon three times a day, a combination of calcium lactate and sodium citrate, or an injection of 2 ml. of mersalyl might be tried. Neither anterior nor posterior pituitary extracts were of value. Chorionic gonadotropin might help in cases associated with delayed puberty; œstrogens tended to increase rather than diminish weight. Exercise was of limited value, and so-called secret remedies depended for any success on concomitant dieting.

Attention was drawn to pregnancy and postpartum "obesity," and recent observations on overactivity of growth hormone leading to large babies and maternal "obesity," due to depletion of fat stores in order to provide the energy for laying down protein. This was one example of obesity not due to over-eating.

Reviews of Books

Among the Doctors

Alfred Cox, M.D., formerly secretary of the British Medical Association. London: Christopher Johnson. 1950. Pp. 224. 12*s.* 6*d.*

In this book Dr. Cox, from old age, looks back upon a long life largely devoted to the service of the British Medical Association. The most interesting reminiscences of those who have played a prominent part in public affairs are often concerned not with the days of their prominence but with their beginnings and origins in obscurity. Certainly Dr. Cox's account of his work as an unqualified assistant to a succession of practitioners, some respectable, some sad rascals, has as much of interest in it as have his later experiences of contacts with the heads of the profession at B.M.A. House or on his many journeys. Thus his portrait studies of seven medical peers as he knew them are conventional respectful portraits with little of the character and flavour of his earlier studies of the colliery doctors of the 1890s.

Dr. Cox writes simply and modestly of his own achievements and upon matters of which few but himself can now have had personal experience. His comparison between the reconstructions of the profession in 1911 and in 1948, and between Mr. Lloyd George and Mr. Aneurin Bevan as negotiators, is the most important part of a book which will be read with interest by many.

Coagulation, Thrombosis, and Dicumarol

Shepard Shapiro, M.D., assistant professor of clinical medicine, New York University College of Medicine; Murray Weiner, M.S., M.D., fellow in medicine at the college. New York: Brooklyn Medical Press. 1949. Pp. 131. $5.50.

This book is a short and well-balanced account of current views on the physiology and pathology of blood-coagulation and of clotting in blood-vessels, followed by a thorough discussion of the use of anticoagulant therapy with heparin and dicoumarol. It is not a "one-school" book: the authors present all sides fairly and give proper references. But having done this, they clearly state their own views and take a definite stand on techniques and on methods of treatment. This gives the book real practical value, and those who adopt the methods recommended are likely to have as much success as is possible in the application and control of anticoagulant treatment. We are glad to see that the "one-stage" method of prothrombin estimation is advised and that techniques using snake-venom are decisively rejected. Dr. Shapiro and Dr. Weiner describe an original method of estimating clotting-time by using a rotating tube. The technical section is full of interest, and with each method there is a section of "useful hints" which reveal the authors' experience. Every worker in this field will probably find points at which he disagrees, but this is as reasonable an introduction to the subject as we have seen.

Pollen Slide Studies

Grafton Tyler Brown, M.D., F.A.C.P., consultant on allergy, United States Public Health Service. Springfield, Ill.: C. C. Thomas. Oxford: Blackwell Scientific Publications. 1949. Pp. 122. 43*s.*

The aim of this book is to "enable any allergist or technician to identify and count the important pollen grains and larger fungus spores that are present in the air in sufficient numbers to be breathed in with normal respiration." Dr. Brown traps pollen from the air in the usual way—by exposing an adhesive-covered and horizontally placed microslide. The circular shelter which he shows in position over the slide would be insufficient to keep off British rain. His statement that the pollen is deposited on the slide by gravity (though this is now known to be true only in part) is unfortunately typical of his rather uncritical account of the principles underlying the estimation of airborne pollen populations. He quotes his own analyses of pollen caught on daily slides exposed, as he says, "in the District of Columbia"—an area of some 61 square miles. He does not state close to the fracture; in the other the operation was undertaken too soon. The strong tendency for pseudarthrosis to persist despite the usual forms of conservative and operative treatment was due entirely to mechanical factors; immobilisation was not sufficiently complete to overcome the bending stresses that were so inimical to the formation of lamellar bone. Pseudarthrosis of the tibia was neither a birth fracture nor a non-fusion of two separate centres of ossification: it was a stress fracture in a tibia that was congenitally abnormal. The abnormality was in the mesenchyme, and it might give rise to a cyst or to an area of slender bone of inadequate strength. Pseudarthrosis had been produced experimentally in chickens by injecting insulin into the embryo at the appropriate period of development.

V-arthrodesis of the hip.—Mr. R. C. HOWARD (Norwich) described a method of arthrodesis of the hip, developed in association with Mr. H. A. BRITTAIN, in which fixation of the joint by a nail was combined with ischiofemoral grafting. The bed for the graft was prepared by passing a wide-diameter drill through the upper part of the femoral shaft into the ischium. The nail and the graft formed a V, which made for mechanical rigidity. Prolonged immobilisation in plaster was unnecessary, and walking with crutches was permissible within a few weeks of the operation. The main indication for the operation was unilateral osteo-arthritis of the hip. Sound bony fusion had been secured in 14 of 17 patients.

Oblique osteotomy for osteo-arthritis of the hip.—Mr. G. V. OSBORNE (Liverpool) had reviewed 75 cases in which oblique displacement osteotomy of the femur had been performed for osteo-arthritis of the hip. He emphasised the importance of careful selection of cases for this operation. The most suitable patients were those with gross osteo-arthritis and fixed adduction deformity. The operation should be avoided when a free range of abduction remained, and when marked flexion deformity could not be corrected by preliminary manipulation; in such cases loss of contact between the osteotomy surfaces might lead to non-union. The mechanical disadvantage of the hip—due to leverage factors—was such that the thrust through the joint was equal to at least twice the weight of the body, and much more when adduction deformity was present. Displacement osteotomy overcame this mechanical disadvantage. It reduced leverage by bringing the line of body-weight near to the axis of the femoral shaft, and by affording a bony block to prevent adduction. The operation had been successful in relieving pain and restoring adequate function in 61 cases, and unsuccessful in 14. Many of the failures were attributable to errors of technique.
